(Dated: November 20, 2021)

We study the Tan’s contact of a one dimensional quantum gas of $N$ repulsive identical bosons confined in a harmonic trap at finite temperature. This canonical ensemble framework corresponds to the experimental conditions, the number of particles being fixed for each experimental sequence. We show that, in the strongly interacting regime, the contact rescaled by the contact at the Tonks-Girardeau limit is an universal function of two parameters, the rescaled interaction strength and temperature. This means that all pair and correlation effects in the Tan’s contact are embedded in the Tan’s contact in the Tonks-Girardeau limit.

I. INTRODUCTION

Many-body quantum physics is a cornerstone of modern physics and a key to understand future technologies such as high $T_c$ superconductivity or quantum computing. However, an accurate description of strongly correlated quantum systems, for an arbitrary number of particles, is often a dare without a simple solution. Apart from the very specific family of integrable systems [1–11], where all observables can, in principle, be predicted theoretically, our knowledge is in general limited to simple situations like two particles [12–14], solutions that hold in the thermodynamic limit [15–19], or mean-field descriptions for many-body systems [17, 18]. It is therefore quite delicate to extract general informations such as the scaling of physical observables with respect to the number of particles for generic situations.

For the case of quantum particles with point-like interactions, short-range correlations are embedded in the Tan’s contact $C_N$ [20–22]. This quantity, that is proportional to the probability that two particles approach each other infinitely close, determines the asymptotic behaviour of the momentum distribution $n(k)$, $C_N = \lim_{k \to \infty} k^4 n(k)$, $k$ being the momentum divided by $\hbar$. This observable can be measured via time-of-flight techniques [23–25], with radio-frequency spectroscopy [26–27], Bragg spectroscopy [28], by measuring the energy variation as a function of the interaction strength [24], or by looking at three-body losses in quantum mixtures [29]. This central quantity is a function of the interaction energy, density-density correlations function, the trapping configuration, the temperature as well as the magnetization [30–31], and thus depends in a non trivial way on the nature and the number $N$ of particles. Therefore, even in one dimension, the behaviour of $C_N$ is not completely clarified, especially in trapped systems, despite many theoretical investigations [32–35]. For one-dimensional (1D) bosons (and/or fermions) trapped in a harmonic potential of frequency $\omega$, it has been shown that, in the thermodynamic limit, at zero temperature, the contact rescaled by $N^{5/2}$ is a universal function of one scaling parameter: $z = a_{ho}/(a_{1D} \sqrt{N})$ [15–34]. This holds also at finite temperature, in the grand-canonical ensemble: the contact rescaled by $N^{5/2}$ is a universal function of two scaling parameters, $z$ and $T_F = |a_{1D}|/\lambda_{DB}$, or equivalently $z$ and $\tau = T/T_F$ [16–36], $a_{1D}$ being the 1D scattering length, $a_{ho} = \sqrt{\hbar/(m \omega)}$ the harmonic oscillator length, $m$ being the mass, $\lambda_{DB} = \sqrt{2\pi \hbar^2/m k_B T}$ the De Broglie thermal wavelength, $T_F = N\hbar/\k_B$ the Fermi temperature, and $k_B$ the Boltzmann constant. However, for systems with small number of particles, the $N^{5/2}$-scaling fails. In the zero-temperature limit [37], it is possible to change the paradigm and to introduce a different scaling form that holds from $N = 2$ to infinity. At finite temperature, in the grand-canonical ensemble, the $N^{5/2}$-scaling holds for $N > 10$ [16]. However, corrections at small number of particles have, to our knowledge, not yet been studied in 1D, and the important question of the relevance of the statistical ensemble has not been addressed. The latter is indeed a crucial point since ultracold atom experiments are canonical or, more often, an average over canonical ensembles, but not grand canonical and scaling properties are obviously strongly affected by the statistical distribution of particles numbers. In fact, in ultracold experiments, in each experimental sequence, $N$ atoms are charged in a three-dimensional trap. Then the atoms are separated in several light wires created by the interference of two propagating laser beams [38]. The atomic gas in the wires can be considered as one-dimensional, if the interaction and thermal energies are lower than the energy scale of the radial confinement $\hbar \omega_{\bot}$, $\omega_{\bot}$ being the radial harmonic oscillator frequency [39]. Otherwise, atoms can be directly trapped in a single 1D tube with a strong radial confinement [40]. In both cases, the relation between the 1D scattering length $a_{1D}$ and the 3D one $a_{3D}$ is given by $a_{1D} = -a_{3D}^2/\omega_{3D}$, where $a_{3D} = \sqrt{\hbar/(m \omega_{3D})}$ [41].

In this paper we study the canonical Tan’s contact for a small number of harmonically trapped Lieb-Liniger bosons.

We show that, in the strongly interacting regime, the
contact for \( N \) bosons at temperature \( T \) and with repulsive interaction, divided by the contact for the same number of bosons and temperature but in the regime of infinite repulsions, is a \( N \)-independent function of \( z \) and \( \tau \). Namely, all the non-trivial particle-number dependence is embedded in the contact in the infinite interaction limit, even at finite temperature, which is the main result of this work. The regime of infinite repulsions in one-dimension corresponds to the so-called Tonks-Girardeau limit. In this regime, the infinite repulsions, due to the low-dimensionality, play the role of a sort of Pauli principle so that bosons “behave” as non-interacting fermions. Another result is that we provide an analytical expression for the \( N \)-dependence of the canonical contact in the Tonks-Girardeau limit. Our formula is a conjecture that works extremely well over the whole temperature range. The consequence of these two results is that we can explicitly express the canonical contact for \( N \) harmonically trapped Lieb-Liniger bosons in the intermediate and strong-interaction regime \((z > 1)\), for any value of \( N \) and any temperature \( T \).

The paper is organized as follows. In Sec. II we introduce the physical system and define the canonical Tan’s contact. This observable is then evaluated exactly in two special situations: for two identical bosons at any interaction strength and any temperature and for \( N \) identical bosons in the Tonks-Girardeau limit (infinite coupling). In the general situation, namely for intermediate interaction strength and for \( N > 2 \), we calculate the Tan’s contact by means of Quantum Monte Carlo (QMC) simulations. The scaling properties of the canonical contact are then analyzed in Sec. III. After reminding the results previously obtained, in the strongly-interacting limit, at zero temperature \([31]\), we analyze the large temperature scaling of the contact in the same limit. By comparing these two limits, we propose an explicit form of the contact scaling function holding in the strongly interacting limit and at any temperature which makes our numerical data overlap for different number of atoms \( N \) with only a few percent discrepancy. In Sec. IV we compare the canonical contact with the grand-canonical one. At large temperature the canonical and grand-canonical contacts are both proportional to the two-bosons contact. This does not hold at smaller temperatures. Finally, our concluding remarks are given in Sec. V.

II. CANONICAL TAN’S CONTACT

We consider a gas of \( N \) identical interacting bosons of mass \( m \) trapped in a 1D harmonic confinement. This system is described by the Hamiltonian

\[
H = \sum_{i=1}^{N} \left( \frac{\hbar^2}{2m} \frac{\partial^2}{\partial x_i^2} + \frac{1}{2} m \omega^2 x_i^2 \right) + g \sum_{i<j} \delta(x_i - x_j),
\]

where the repulsive interaction strength \( g \) depends on the 1D scattering length as \( g = -2 \hbar^2/ma_{1D} \), if \( a_{1D} \gg a_{3D} \)

[41]. At finite temperature \( T \), in the canonical ensemble, the contact for \( N \) bosons, \( C_N^c(g, T) \), can be deduced from the free energy \( F \) by exploiting the Tan’s sweep relation

\[
C_N^c(g, T) = -\frac{m^2}{\pi \hbar^4} \frac{\partial F}{\partial g},
\]

\[
= -\frac{m^2}{\pi \hbar^4} \sum \frac{e^{-\beta E_i}}{\sum_i e^{-\beta E_i}},
\]

where \( E_i \) is the \( i \)-th eigenenergy of the \( N \)-boson system and \( \beta = (\hbar B)^{-1} \). \( C_N^c(g, T) \) can be exactly evaluated for \( N = 2 \) at any value of the interaction strength \( g \) and any temperature \( T \), and in the Tonks-Girardeau limit \( g \to \infty \) for any \( N \) and \( T \).

Let us underline that, analogously to the zero-temperature case, the contact can also be calculated from the average interaction energy that can be obtained by the free energy from the Hellmann-Feynman theorem \( \langle H_{\text{int}} \rangle = g \partial F/\partial g \) [42]. It follows [21]

\[
C_N^c(g, T) = \frac{g n^2}{\pi \hbar^4} \langle H_{\text{int}} \rangle.
\]

A. The two bosons system

For the two bosons system, the energy spectrum can be calculated analytically. In this case \( E_i = E_{\text{cm},\ell} + E_{r, j}, E_{\text{cm}, \ell} \) being the centre of mass energy with quantum number \( \ell \) and \( E_{r, j} = \hbar \omega (1/2 + \nu_j) \) the relative energy, with quantum number \( j \) \([i = (\ell, j)]\), that depends on the interaction strength via the implicit relation [12]

\[
f(\nu) = \frac{\Gamma(-\frac{\nu}{2})}{\Gamma(-\frac{\nu}{2} + \frac{1}{2})} = -\sqrt{2} \frac{a_{1D}}{a_{ho}},
\]

where \( \Gamma(x) \) is the gamma function [13]. \( E_{\text{cm}, \ell} \), differently from the relative energy \( E_{r, j} \), is completely independent on interatomic interactions as stated by the Kohl’s theorem [14] and then does not contribute to the contact calculation. By applying Eq. (2), the two bosons contact then takes the form

\[
C_2^c(g, T) = \frac{\sqrt{8 \pi z}}{\pi a_{ho}} Z_r^{-1} \sum_j e^{-\beta \hbar \omega \nu_j} \frac{\partial \nu_j}{\partial z}
\]

\[
= \frac{\sqrt{32 \pi z}}{\pi a_{ho}^3} Z_r^{-1} \sum_j e^{-\beta \hbar \omega \nu_j} \frac{\Gamma(-\frac{\nu_j}{2} + \frac{1}{2})}{\Gamma(-\frac{\nu_j}{2})}
\]

\[
\times \left[ \psi\left( -\frac{\nu_j}{2} + \frac{1}{2} \right) - \psi\left( -\frac{\nu_j}{2} \right) \right]^{-1},
\]

where \( Z_r = \sum_j e^{-\beta \hbar \omega \nu_j} \) is the canonical relative motion partition function and \( \psi(x) = \Gamma'(x)/\Gamma(x) \) is the digamma function [13]. In the Tonks-Girardeau limit \( \nu_j = 2j - 1 \) \((j \geq 1)\) and both \( \Gamma(-\frac{\nu_j}{2} + \frac{1}{2}) = \Gamma(-\nu_j + 1) \)
and \( \psi \left( - \frac{a_0}{\sqrt{2}} + \frac{1}{2} \right) = \psi(-j + 1) \) diverge for \( j \geq 1 \). With some algebra, it can been shown that

\[
C_2^c(\infty, T) = \frac{\sqrt{32}}{\pi^{3/2} a_0^3} Z^{-1}_r \sum_j e^{-\beta \hbar \omega (2j - 1)} \frac{(2j - 1)!!}{2j(j - 1)!} \tag{6}
\]

Remark that Eq. (6) gives the known limit \( C_2^c(\infty, 0) = (2/\pi)^{3/2} a_0^{-3} \) \cite{37}. The canonical two-bosons contact obtained by Eq. (5) is shown in Fig. 1. We have verified that the curve for \( z = 1000 \) is essentially indiscernable from the contact evaluated in the Tonks limit by means of Eq. (6).

**B. The Tonks-Girardeau limit**

In the Tonks-Girardeau limit, where fermionization occurs, the interaction strength \( g \) is infinite, namely the 1D scattering length \( a_{1D} \) is zero and therefore, this length-scale disappears by making the problem more universal. Thus the contact, in this regime, does not depend on the interactions and can be written as a function of the corresponding fermionic two-body density matrix \( \rho_{2F}(x_1, x_2; x_1', x_2') \) \cite{15}. More precisely, it can be shown that

\[
C_N^c(\infty, T) = \frac{2}{\pi} \int_{-\infty}^{+\infty} dx F(x) \tag{7}
\]

where we have defined

\[
F(x) = \lim_{x', x'' \to x} \rho_{2F}(x', x; x'', x) \frac{1}{|x - x'| |x - x''|} \tag{8}
\]

By explicitly expressing \( \rho_{2F} \) in the canonical ensemble, as a function of the single-particle orbitals \( u_i(x) \), we get

\[
F(x) = Z^{-1} \sum_{i_1 = 0, \infty, i_2 = i_1 + 1, \infty} e^{-\beta \hbar \omega \sum_{j=1}^{N_F} (i_j + \frac{1}{2})} \sum_{(j, k)} \left( |u_{i_j}(x)\partial_x u_{i_k}(x)|^2 - 2u_{i_j}(x)\partial_x u_{i_k}(x)u_{i_k}(x)\partial_x u_{i_j}(x) \right) \tag{9}
\]

with

\[
Z = \sum_{i_1 = 0, \infty, i_2 = i_1 + 1, \infty} \cdots i_{N_F} = i_{N_F} + 1, \infty e^{-\beta \hbar \omega \sum_{j=1}^{N_F} (i_j + \frac{1}{2}).} \tag{10}
\]

The canonical contact \( C_N^c(\infty, T) \), as obtained by Eqs. (7) and (10), is shown in Fig. 2 (empty symbols) for \( N = 2 \) to 5. The data are compared with grand-canonical ones \cite{46} (full symbols) that will be discussed below (Sec. IV). Remark that the computation of the contact is more demanding in the canonical case than in the grand-canonical one, because of several sums in (9) that simplify in the grand-canonical case.

**C. The finite interaction strength regime**

In the finite interaction strength scenario for \( N > 2 \), we rely on quantum Monte Carlo simulations to obtain exact results. Starting from Eq. (1), we discretize the Hamiltonian using a finite difference method and rewrite it using second quantization, ending with the following...
bosonic Hubbard Hamiltonian
\[ H = -t \sum_j \left( b_j^\dagger b_{j+1} - 2n_j + b_j^\dagger b_{j-1} \right) + w \sum_j j^2 n_j + U \sum_j n_j(n_j - 1)/2. \]  
(11)

The discrete positions of the bosons are given by \( x = j \Delta a_{ho} \) where \( \Delta \) is a small dimensionless parameter. We typically used \( \Delta = 0.1 \) and checked on some simulations that the systematic errors induced by this discretization were smaller than the stochastic errors due to the Monte Carlo calculations. The operators \( b_j^\dagger \) and \( b_j \) create or destroy bosons on site \( j \). \( n_j = b_j^\dagger b_j \) is the bosonic number operator on site \( j \). The parameters are given by
\[ t = \frac{\hbar \omega}{2 \Delta^2}, \quad w = \frac{\hbar \omega \Delta^2}{2}, \quad U = \frac{g}{\Delta a_{ho}}. \]  
(12)

The Hubbard model is simulated using the stochastic Green function algorithm \([17, 18]\) that allows the calculation of many physical quantities for finite systems at finite temperature. The algorithm works in both canonical and grand-canonical ensembles, although it is generally more efficient in the former case. Grand canonical simulations require the sampling of a larger space containing different numbers of particles, which increases a lot the correlation time of the data, as the sampling of different \( N \) is not very efficient. Remark that, in the grand canonical ensemble, it is then sometimes difficult to pinpoint a precise value of \( \langle N \rangle \) as it requires a fine tuning of the chemical potential \( \mu \).

We will concentrate on small number of particles \( N \), which gives a more thorough test of the scaling hypotheses we will introduce at they should be valid for large \( N \).

Using this algorithm, we calculate the average interaction energy \( \langle H_{\text{int}} \rangle \) that gives access to the contact \([37]\). We choose a system size large enough so density becomes zero at the edges of the system. As the temperature \( T \) increases, the simulations become increasingly difficult: the density distribution of the particles becomes wider, which means that the events where two particles are superposed and then contributes to the interaction energy become rare, giving a poor signal to noise ratio for the contact calculation. Increasing interactions also reduces the probability of double occupancies and, consequently, the precision of the calculation.

These difficulties are further enhanced by the fact that, as \( N \) increases, we will maintain fixed rescaled temperature \( \tau = t/T \) and interaction \( z = g/\hbar \omega a_{ho}^2 \) to observe possible scaling behaviours. The temperature \( T \) and interaction \( g \) will then scale with number of particles as \( N \) and \( \sqrt{N} \), respectively. These combined effects strongly limits the temperatures, interactions, and number of particles for which we obtain reliable results. For canonical simulations, we were able to obtain results with a relative error better than two per cent for rescaled interactions up to \( z = 2.5 \), rescaled temperatures up to \( \tau = 5 \) and numbers of particles up to \( N = 5 \). Grand canonical results are more limited. For \( N \) up to 4, we are limited to \( z = 1 \) and \( \tau = 0.2 \) if we want a precision of few percents. For \( N = 4 \), \( z = 1 \) and \( \tau = 2 \), we have relative errors of order 20\%, which hardly give meaningful information.

### III. SCALING PROPERTIES

#### A. Zero temperature scaling

In \(37\) we have shown that it is possible to express the contact for \( N \) bosons or \( N \) \( SU(k) \)-fermions as a function of the contact for two bosons. Indeed the reduced contact
\[ f_N(z, 0) = \frac{C_N(g(z), 0)}{C_N(\infty, 0)}, \]  
(13)
with \( g(z) = 2\hbar^2 Nz/(ma_{ho}) \), verifies the relation \(37\)
\[ f_N(z, 0) \approx f_2(z, 0), \]  
(14)
meaning that, upon rescaling of the interaction strength, all the \( N \)-dependence of the contact is in \( C_N(\infty, 0) \). Moreover it has been shown from a fit on numerical data \(37\) that
\[ C_N(g(z), 0) \sim N^{5/2} - \gamma N^\eta \]  
(15)
where \( \gamma \simeq 1 \) and \( \eta = 3/4 \) in the Tonks-Girardeau limit, and where they are slowly varying in the strongly interacting regime \( z > 1 \).

#### B. Large temperature scaling

In the large temperature limit, \( T \gg T_F \), quantum correlations are negligible and the contact for \( N \) bosons in the canonical ensemble is simply given by the two-particle contact times the number of pairs
\[ C_N^c(g, T \gg T_F) = \frac{N(N-1)}{2} C^c_2(g, T \gg T_F). \]  
(16)

In the strongly interacting limit Eq. \(16\) takes the explicit form (see Appendix)
\[ C_N^c(z > 1, \tau \gg 1) = \frac{N(N-1)}{2} \frac{2g}{\pi^{3/2} \hbar \omega a_{ho}^2} \sqrt{\alpha} \left( 1 - \sqrt{\frac{\pi}{\alpha}} e^{1/\alpha} \text{Erfc}(1/\sqrt{\alpha}) \right) \]  
(17)

with \( \alpha = 4a_{ho}^2 \hbar \omega/(\beta g^2) = \tau/z^2 \) and
\[ h_N(z > 1, \tau \gg 1) = \frac{2z}{\pi^{3/2} a_{ho}^2} \sqrt{\alpha} \left( 1 - \sqrt{\frac{\pi}{\alpha}} e^{1/\alpha} \text{Erfc}(1/\sqrt{\alpha}) \right). \]  
(18)
In the Tonks-Girardeau limit
\[
C_N^c(\infty, \tau \gg 1) = \frac{N(N-1)}{2} \frac{2}{\pi^{3/2}a_0^3} \sqrt{\frac{k_B T}{\hbar \omega}}
\]
\[
= (N^{5/2} - N^{3/2}) h_N(\infty, \tau \gg 1)
\]
with
\[
h_N(\infty, \tau \gg 1) = \frac{1}{\pi^{3/2}a_0^3} \sqrt{\tau}.
\]
Analogously to the zero temperature case, we can define the function
\[
f_N(z > 1, \tau \gg 1) = \frac{C_N(g(z), T(\tau))}{C_N(\infty, T(\tau))},
\]
and we get that
\[
f_N(z > 1, \tau \gg 1) \simeq f_2(z > 1, \tau \gg 1)
\]
holds in the limit \(T \gg T_F\), with \(f_2(z > 1, \tau \gg 1) = h_2(z > 1, \tau \gg 1)/h_2(\infty, \tau \gg 1)\).

C. Any temperature scaling conjecture

We now propose the general scaling hypothesis that Eq. (22) holds for any temperature in the strong-interaction limit. This is equivalent to claim that, upon rescaling of the interaction strength and of the temperature, all the \(N\)-dependence of the contact is embedded in \(C_N(\infty, T, \tau)\), for any temperature. This dependence is quite trivial at large temperature, as it is determined by the number of pairs, proportional to \(N(N-1)\), and a \(\sqrt{N}\) term that comes from the rescaling of the temperature with respect to the Fermi temperature. By lowering the temperature, the contact almost freezes at \(T \simeq T_F\) and, because of quantum correlations, there is an enhancement of the dependence on \(N\), from \(N^{5/2} - N^{3/2}\) to \(N^{5/2} - N^{3/4}\). This leads us to propose the following conjecture
\[
C_N^c(\infty, \tau) = h_2(\infty, \tau) s(N)
\]
\[
= h_2(\infty, \tau) \left( N^{5/2} - N^{3/4}(1+\exp(-2/\tau)) \right),
\]
where
\[
h_2(\infty, \tau) = C_2(\infty, T(\tau))/s(2)
\]
can be derived by Eq. (9). In Fig. 3 we plot \(C_N^c(\infty, T)\) [Eq. (7)], divided by \(s(N)\), as a function of \(\tau\), for cases from \(N = 2\) to \(N = 5\), as well as \(h_2(\infty, \tau)\), its high-temperature limit \(h_2(\infty, \tau \gg 1)\) and its value at zero temperature \(h_2(\infty, 0)\). All the data collapse on the same curve \(h_2(\infty, \tau)\) (continuous black curve), showing that the conjecture (24) works extremely well.

We test now the reliability of the generalized scaling hypothesis
\[
f_N(z > 1, \tau) \simeq f_2(z > 1, \tau)
\]
approaching the strongly interacting regime. In Figs. 4 and 5 we plot the canonical contact, obtained from quantum Monte-Carlo simulations, for the cases \(z = 1\) and 2.5, respectively. For both figures 4 and 5 in panels (a) the data have been rescaled by \(N^{5/2} - N^{3/4}\), in panels (b) by \(N^{5/2} - N^{3/2}\), and in panels (c) by \(s(N)\). The “zero-temperature” scaling factor \(N^{5/2} - N^{3/4}\), as obtained in [37] for the Tonks-Girardeau limit, makes, at small temperatures, the curves approach at \(z = 1\) and collapse at \(z = 2.5\). The “pair scaling” term \(N^{5/2} - N^{3/2}\) works well in the large temperature regime \(\tau > 1\), while the interpolating function \(s(N)\) [Eq. (23)] allows the collapse of the data in the whole temperature range, with an incertitude of 5% for the case \(z = 1\) (Fig. 4(c)) and of 1% for the case \(z = 2.5\) (Fig. 5(c)). The validity of the scaling hypothesis (24) is verified in Figs. 4 d and 5 d. Remark that, as mentioned earlier, precise QMC results are limited to small number of particles and intermediate values of \(\tau\) and \(z\). The limitation on the number of particles is not crucial as, for large number of particles, \(\lim_{N \to \infty} s(N)/N^{5/2} = 1\), and we recover the known thermodynamics limit. Concentrating on small number of particles \(N \leq 5\) then provides a more stringent verification of the reliability of the scaling hypothesis (25).

IV. COMPARISON WITH THE GRAND-CANONICAL TAN’S CONTACT

In the zero temperature limit, the grand-canonical and canonical contacts coincide, thus, in the strongly interacting regime, both scale as \(\sim (N^{5/2} - N^{3/4})\).

But, as soon as the temperature increases, the grand-
FIG. 4: Panels (a), (b) and (c): \( C_N(z, \tau) a_h^3 \) as a function of \( \tau \), for the case \( z = 1 \), rescaled by \( N^{5/2} - N^{3/4} \) (a), \( N^{5/2} - N^{3/2} \) (b), and \( s(N) \) (c). Panel (d): \( f_N(z = 1, \tau) \) as a function of \( \tau \). The points (violet squares: \( N = 2 \), green circles: \( N = 3 \), light-blue up-triangles: \( N = 4 \) and orange down-triangles: \( N = 5 \)) correspond to the QMC data. The continuous yellow line corresponds to the two-bosons contact obtained by Eq. (5). Non visible QMC error bars are smaller than the symbol size.

FIG. 5: Panels (a), (b) and (c): \( C_N(z, \tau) a_h^3 \) as a function of \( \tau \), for the case \( z = 2.5 \), rescaled by \( N^{5/2} - N^{3/4} \) (a), \( N^{5/2} - N^{3/2} \) (b), and \( s(N) \) (c). Panel (d): \( f_N(z = 2.5, \tau) \) as a function of \( \tau \). The points (violet squares: \( N = 2 \), green circles: \( N = 3 \), light-blue up-triangles: \( N = 4 \) and orange down-triangles: \( N = 5 \)) correspond to the QMC data. The continuous yellow line corresponds to the two-bosons contact obtained by Eq. (5). Non visible QMC error bars are smaller than the symbol size.
canonical contact for an average number $\langle N \rangle$ of particles departs from the canonical one for $N$ particles. Indeed, with larger numbers contributions, the grand-canonical contact increases more rapidly than the canonical one that is almost constant for $0 \leq \tau \leq 0.4$ (see Fig. 2 for the Tonks-Girardeau limit case).

In the large temperature limit, in the grand-canonical ensemble, the term $N(\langle N - 1 \rangle)$ proportional to the number of pairs in the canonical ensemble, has to be replaced by its average value

$$\langle N(\langle N - 1 \rangle) \rangle = \langle N^2 \rangle - \langle N \rangle = \langle N \rangle^2. \tag{26}$$

This follows from the fact that, at large $T$, $\langle \Delta N^2 \rangle \simeq \langle N \rangle$. By defining $T_F = \langle N \rangle \hbar \omega/k_B$, we find

$$C_N^{\text{gc}}(g,T \gg T_F) = \frac{\langle N \rangle^2}{2} = \langle N \rangle^{5/2} h_2(z > 1, \tau \gg 1), \tag{27}$$

in agreement with the virial calculation Ref. 10. Thus, in the large temperature limit, $C_N^{\text{gc}}(g,T \gg T_F)/\langle N \rangle^{5/2}$ and $C_N(g,T \gg T_F)/(N^{5/2} - \bar{N}^{5/2})$ collapse on the same curve $h_2(z, \tau \gg 1) = \sqrt{\tau}/(\pi^{3/2}a_\text{ho}^2)$. This is shown in Fig. 6 for the Tonks-Girardeau limit, where we have compared the canonical contact [Eq. (7)] and the grand-canonical one as obtained from Eqs. (8)-(9) in Ref. 46. Remark that the convergence is faster for the grand-canonical contact. The consequence of the fact that the canonical and the grand-canonical contact are proportional to one another, at large temperature $\tau \gg 1$, is that both have a maximum at $\tau = 1.48 z^2$ in the strong-interacting limit Ref. 10. The situation is different in the weak-interaction regime, where the grand-canonical contact exhibits a maximum at lower temperatures. This maximum, that has been explained as the mark of the crossover between a quasicondensate and an ideal Bose gas Ref. 16, is not present in the canonical case. This has been studied by means of QMC simulations and shown in Fig. 7.

In the canonical ensemble and at low interactions the contact decreases with increasing temperature because, as particles occupy individual excited states, the cloud of particles spreads and the interaction energy is lowered. This happens when the temperature is large enough to overcome the $\hbar \omega$ gap between the ground and excited states, which explains why there is almost no variation at low temperature.

In the grand canonical ensemble, the same effect will of course take place and yields to the same decrease of the contact at high temperature. However, at low temperature, another phenomena occurs: the probability to have a number of particles that is larger than $\langle N \rangle$ increases with temperature. This gives larger contributions to the interaction energy and explains the initial increase of the contact at low temperatures.

As Eq. 22 holds even in the grand-canonical ensemble, one may wonder if the generalized scaling hypothesis Ref. 25 is still valid in this ensemble. In Fig. 8 we plot the quantity $C_N^z(z,\tau)/C_N^\text{gc}(\infty,\tau)$ for the case $z = 1$ and $N = 2, 3$ and $4$ and $\tau \leq 2$, $C_N^z(z,\tau)$ having been calculated by means of QMC simulations and $C_N^\text{gc}(\infty,\tau)$ by means of Eqs. (8)-(9) in Ref. 46. We observe that, for small and intermediate temperatures, in the intermediate interactions regime, the curves remain different, instead of the collapse observed in the canonical case (see Fig. 4d)). Our scaling hypothesis then fails in this case of intermediate interactions, as the grand-canonical Tonks-Girardeau contact does not embed the full $\langle N \rangle$-dependency for these intermediate interactions. We were not able to test this
for any number of particles and temperature. This enlightens the dependence of the analytical formula for the second for any number of bosons. The first can be easily calculated and we provide an analytic formula for the second for any number of bosons and temperature. This enlightens the dependence of the contact on the number of pairs at large temperature and the effects of correlations at low temperature. Moreover, it supplies a scaling function, in the canonical ensemble, for any number of particles $N \geq 2$ and any temperature in the strong interacting regime. We have proven our theory for small number of bosons ($2 \leq N \leq 5$) where corrections with respect to the known thermodynamic limit are more important. We have been informed that these results may also hold true for a 1D homogeneous Bose gas. This can be deduced from the results recently presented in [49]. In this paper the authors show that these results may also hold true for a 1D homogeneous system of linear density ($P/T$) which is equivalent for an homogeneous system of the homogeneous system of linear density ($P/T$). From this it can be deduced that $C_N^c(z_H > 1, \tau_H)/C_N^c(\infty, \tau_H)$ is also a universal function, which is equivalent for an homogeneous system of the scaling relations found in the trapped case.

Finally we discuss the difference between the canonical and grand-canonical contacts. At large temperature these quantities are both proportional to the two bosons contact, and the proportionality factor depends on the number of pairs in the canonical ensemble and the average number of pairs in the grand-canonical one. The main difference between the grand-canonical and canonical cases is that, at small and intermediate temperatures, the grand-canonical contact for $\langle N \rangle$ bosons cannot be written as a function of the $(2)$-bosons contact and the contact for $\langle N \rangle$ Tonks-Girardeau bosons, as far as we can test it with the QMC simulations in the intermediate interaction regime. Namely, at variance from the canonical case, the grand-canonical contact for $\langle N \rangle$ Tonks-Girardeau bosons seems not to embed the dependence for the average number of particles $\langle N \rangle$. Indeed our scaling hypothesis fails as far as we can test it with the QMC simulations in the intermediate interaction regime.

Our work can be relevant for experiments with a small number of particles [50, 51]. From a conceptual point of view, it is an important step forward in understanding the effects of correlations and interactions in finite-temperature harmonically trapped one-dimensional bosons, as well as in enlightening the role of the particle-number fluctuations. The extension to the case of multi-component systems is not straightforward and will be the subject of a further study.

V. CONCLUSION

In this paper we have shown that the canonical contact for $N$, harmonically trapped, Lieb-Liniger bosons, at any temperature, in the repulsive strongly interacting regime, can be written as a function of the two-bosons contact and the contact for $N$ Tonks-Girardeau bosons. The first can be easily calculated and we provide an analytical formula for the second for any number of bosons and temperature. This enlightens the dependence of the contact on the number of pairs at large temperature and the effects of correlations at low temperature. Moreover, it supplies a scaling function, in the canonical ensemble, for any number of particles $N \geq 2$ and any temperature in the strong interacting regime. We have proven our theory for small number of bosons ($2 \leq N \leq 5$) where corrections with respect to the known thermodynamic limit are more important. We have been informed that these results may also hold true for a 1D homogeneous Bose gas. This can be deduced from the results recently presented in [49]. In this paper the authors show that these results may also hold true for a 1D homogeneous system of linear density ($P/T$) which is equivalent for an homogeneous system of the homogeneous system of linear density ($P/T$). From this it can be deduced that $C_N^c(z_H > 1, \tau_H)/C_N^c(\infty, \tau_H)$ is also a universal function, which is equivalent for an homogeneous system of the scaling relations found in the trapped case.

Finally we discuss the difference between the canonical and grand-canonical contacts. At large temperature these quantities are both proportional to the two bosons contact, and the proportionality factor depends on the number of pairs in the canonical ensemble and the average number of pairs in the grand-canonical one. The main difference between the grand-canonical and canonical cases is that, at small and intermediate temperatures, the grand-canonical contact for $\langle N \rangle$ bosons cannot be written as a function of the $(2)$-bosons contact and the contact for $\langle N \rangle$ Tonks-Girardeau bosons, as far as we can test it with the QMC simulations in the intermediate interaction regime. Namely, at variance from the canonical case, the grand-canonical contact for $\langle N \rangle$ Tonks-Girardeau bosons seems not to embed the dependence for the average number of particles $\langle N \rangle$. Indeed our scaling hypothesis fails as far as we can test it with the QMC simulations in the intermediate interaction regime.

Our work can be relevant for experiments with a small number of particles [50, 51]. From a conceptual point of view, it is an important step forward in understanding the effects of correlations and interactions in finite-temperature harmonically trapped one-dimensional bosons, as well as in enlightening the role of the particle-number fluctuations. The extension to the case of multi-component systems is not straightforward and will be the subject of a further study.

Acknowledgments

We thank an anonymous referee for many useful suggestions and, in particular, for making us aware that our results hold even in the 1D untrapped Bose gas. P.V. thanks A. Minguzzi for useful discussions. The work of F.T.S. was financed in part by the Coordenacao de Aperfeicoamento de Pessoal de Nivel Superior - Brasil (CAPES) - Finance Code 001.

Appendix A: Two-body contact in the strong interaction and large temperature limit

We start with Eq. (A1).

$$C_N^c = -\frac{m^2 \omega}{\pi h^3} \frac{1}{Z_r} \sum_n e^{-\beta \omega n} \frac{\partial \nu_n}{\partial g^{-1}}.$$  \hspace{1cm} (A1)

It can be shown [12] that, in the strongly interacting limit $z > 1$, the solutions of Eq. (A1) are given by

$$\nu_n \simeq \frac{2}{\pi} \frac{1}{\alpha \cot(2\sqrt{2n + 1} g^{-1} \omega a_{ho}) + 2n},$$ \hspace{1cm} (A2)

with $n \geq 0$. This approximation (A2) becomes more precise at large values of $n$. Thus (A1) reads

$$C_N^c = \frac{4Z_r^{-1}}{\pi^2 a_{ho}^3} \sum_n e^{-\beta \omega \nu_n} \sqrt{2n + 1} \frac{1}{1 + 4(2n + 1)(\omega a_{ho} g^{-1})^2}.$$  \hspace{1cm} (A3)
By replacing in the exponential $\nu_n$ with its value in the Tonks-Girardeau limit, $\nu_n = 2n + 1$, and exploiting that

$$
\int_0^\infty \frac{\sqrt{\pi}}{1 + x^2} e^{-\beta \omega x} dx = \frac{1}{(\beta \omega)^{3/2}} \sqrt{\pi} \left( 1 - \frac{\sqrt{\pi}}{\alpha} e^{1/\alpha} \text{Erfc}(1/\sqrt{\alpha}) \right),
$$

with $\alpha = b^2/(\omega \beta) = 4a_0^2 \hbar \omega / (\beta g^2)$, we have that

$$
C_2^c = \frac{2g}{\pi^{3/2} \hbar \omega a_0^4} \left( 1 - \frac{\sqrt{\pi}}{\alpha} e^{1/\alpha} \text{Erfc}(1/\sqrt{\alpha}) \right).
$$

Remark that Eq. (A5) is valid only in the large temperature limit where replacing the sum with an integral is a valid approximation. Hence, in the Tonks-Girardeau limit, the contact reduces to

$$
\lim_{g \to \infty} C_2^c = \frac{4}{\pi^{3/2} \hbar \omega a_0^4} \sqrt{k_B T / \hbar \omega}.
