ABSTRACT
As the DARPA spoken language community moves towards developing useful systems for interactive problem solving, we must explore alternative evaluation procedures that measure whether these systems aid people in solving problems within the task domain. In this paper, we describe several experiments exploring new evaluation procedures. To look at end-to-end evaluation, we modified our data collection procedure slightly in order to experiment with several objective task completion measures. We found that the task completion time is well correlated with the number of queries used. We also explored log file evaluation, where evaluators were asked to judge the clarity of the query and the correctness of the response based on examination of the log file. Our results show that seven evaluators were unanimous on more than 80% of the queries, and that at least 6 out of 7 evaluators agreed over 90% of the time. Finally, we applied these new procedures to compare two systems, one system requiring a complete parse and the other using the more flexible robust parsing mechanism. We found that these metrics could distinguish between these systems: there were significant differences in ability to complete the task, number of queries required to complete the task, and score (as computed through a log file evaluation) between the robust and the non-robust modes.

INTRODUCTION
For the first two years of the DARPA Spoken Language Program, common evaluation in the ATIS domain has been performed solely with the Common Answer Specification (CAS) protocol [4], whereby a system’s performance is determined by comparing its output, expressed as a set of database tuples, with one or more predetermined reference answers [1]. The CAS protocol has the advantage that system evaluation can be carried out automatically, once the principles for generating the reference answers have been established and a corpus has been annotated accordingly. Since direct comparison across systems can be performed relatively easily with this procedure, we have been able to achieve cross fertilization of research ideas, leading to rapid research progress.

However, CAS evaluation is not without its share of shortcomings. One unfortunate outcome of evaluating systems based on answers retrieved from the flight database is that we cannot separately assess the system’s understanding of the query from its ability to retrieve the correct information and to conform to the prescribed output format. In the best case, researchers may end up spending a considerable amount of time worrying about the form and substance of the answer, which has little to do with language understanding. In the worst case, the results of the evaluation may be down right misleading. Consider the two examples from the February 1992 test-set shown in Figure 1. For Query 1, the system misunderstood the phrase “by six” as meaning “before 6:00 a.m.” Nonetheless, the answer is judged correct, because both the hypothesized and reference answers are the NULL set, i.e., no flights satisfy the set of constraints. For Query 2, the system found 279 flights, but the correct answer is 278. The erroneous extra flight is the one connecting flight in the database shared by two airlines, Delta and USAIR.

Another shortcoming of the present evaluation procedure is that it has no place for interactive dialogue. In a realistic application, the user and the computer are often partners in problem solving, in which the final solution may be best obtained by allowing both sides to take the initiative in the conversation. Since the hu-
man/computer dialogue can vary widely from system to
system, it is impossible to use the data collected from one
system to evaluate another system without making avail-
able the computer's half of the conversation. Even then,
the system being tested becomes an observer analyzing
two sides of a conversation rather than a participant.

To be sure, the current evaluation protocol has served
the community well. The refinements made during the
last year have significantly improved its ability to pro-
vide an objective benchmark. However, as we continue
to press forward in developing useful spoken language
systems that can help us solve problems, we must cor-
respondingly expand the battery of evaluation protocols
to measure the effectiveness of these systems in accom-
plishing specific tasks.

At the March 1991 meeting of the SLS Coordinating
Committee, a working group was formed with the specific
goal of exploring methodologies that will help us evaluate
if, and how well, a spoken language system accomplishes
its task in the ATIS domain. The consensus of the work-
ing group was that, while we may not have a clear idea
about how to evaluate overall system performance, it is
appropriate to conduct experiments in order to gain ex-
perience. The purpose of this paper is to describe three
experiments conducted at MIT over the past few months
related to this issue. These experiments explored a num-
ber of objective and subjective evaluation metrics, and
found some of them to be potentially helpful in deter-
mining overall system performance and usefulness.

\section*{END-TO-END EVALUATION}

In order to carry out end-to-end evaluation, i.e., eval-
uation of overall task completion effectiveness, we must
be able to determine precisely the task being solved, the
correct answer(s), and when the subject is done. Once
these factors have been specified, we can then compute
some candidate measures and see if any of them are
appropriate for characterizing end-to-end system perfor-
ance.

While true measures of system performance will re-
require a (near) real-time spoken language system, we felt
that some preliminary experiments could be conducted
within the context of our ATIS data collection effort \cite{3,2}.
In our data collection paradigm, a typist types the
subject's queries verbatim, after removing disfluencies.
All subsequent processing is done automatically by the
system. To collect data for end-to-end evaluation, we
modified our standard data collection procedure slightly,
by adding a specific scenario which has a unique answer.
For this scenario, the subjects were asked to report the
answer explicitly.

As a preliminary experiment, we used two simple sce-
narios. In one of them, subjects were asked to determine

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|}
\hline
Measurements & Mean & Std. Dev. \\
\hline
Total \# of Queries Used & 4.8 & 1.6 \\
\hline
\# of Queries with Error Messages & 1.0 & 1.4 \\
\hline
Time to Completion (s.) & 166.1 & 66.0 \\
\hline
\end{tabular}
\caption{Objective end-to-end measures.}
\end{table}

the type of aircraft used on a flight from Philadelphia to
Denver that makes a stop in Atlanta and serves break-
fast. Subjects were asked to end the scenario by saying
"End scenario. The answer is" followed by a statement
of the answer, e.g., "End scenario. The answer is Boeing
727." From the log files associated with the session
scenario, we computed a number of objective measures,
including the success of task completion, task completion
time, the number of successful and the number of unsuccess-
ful queries (producing a "no answer" message)\textsuperscript{2}.

We collected data from 29 subjects and analyzed the
data from 24 subjects\textsuperscript{3}. All subjects were able to com-
plete the task, and statistics on some of the objective
measures are shown in Table 2.

\textsuperscript{2}The system generates a range of diagnostic messages, reporting
that it cannot parse, or that it cannot formulate a retrieval query,
etc.

\textsuperscript{3}Data from the remaining subjects were not analyzed, since they
have been designated by NIST as test material.

Figure 1 displays scatter plots of the number of queries
used by each subject as a function of the task completion
time. A least-square fit of the data is superimposed. The
number of queries used is well correlated with the task
completion time ($R = 0.84$), suggesting that this measure
may be appropriate for quantifying the usefulness of sys-
tems, at least within the context of our experiment. Also
plotted are the number of queries that generated a "no
answer" message. The correlation of this measure with
the task completion time is not as good ($R = 0.66$), possibly
due to subjects' different problem solving strategies and
abilities.

\section*{LOG FILE EVALUATION}

We also conducted a different set of experiments to
explore subject-based evaluation metrics. Specifically, we
extracted from the log files pairs of subject queries and
system responses in sequence, and asked evaluators to
judge the clarity of the query (i.e., clear, unclear, or un-
intelligible) and the correctness of the response (correct,
partially correct, incorrect, or "system generated an error
message"). A program was written to enable evaluators
to enter their answers on-line, and the results were tab-
ulated automatically. We used seven evaluators for this
experiment, all people from within our group. Four peo-
ple had detailed knowledge of the system and the desig-
nated correct reference answers. Three of the evaluators were familiar with the ATIS system capabilities, but did not have a detailed knowledge of what constituted a correct reference answer for the comparator. Our analyses, based on data from 7 evaluators, indicate that 82% of the time there was unanimous agreement among the evaluators, and there were 1 or fewer disagreements 92% of the time.

These results suggest that reasonable agreement is possible using humans to evaluate log files. Such on-line evaluation is also quite cost effective; the evaluators were each able to check the 115 query/answer pairs in 30-45 minutes.

**SYSTEM COMPARISON EXPERIMENT**

Building on the results of the pilot experiments on end-to-end and log file evaluation, we designed an experiment to test whether these metrics would be useful in distinguishing the performance of two systems on a more complex set of tasks.

**Experimental Design**

We decided to compare the performance of two MIT systems: the “full parse” system and the “robust parse” system [5]. These two systems contrast a conservative approach that only answers when it is confident (the full parse system) against a more aggressive approach that is willing to make mistakes by answering much more often, based on partial understanding (the robust parse system). These systems had very measurably different performance in terms of the CAS metric, and our hypothesis was that the metrics would show that the robust-parsing system outperformed the full-parsing system. To try to capture a broader range of user behavior, we decided to vary the difficulty of the scenarios; we used two pairs of scenarios, where each pair consist of an “easy” scenario followed by a “hard” scenario. The scenarios were chosen to have a single correct answer. The easy scenarios were scenarios adapted from our previous data collection and could be solved with around three queries. The more difficult scenarios were constructed to require more queries (10-15) to solve them. The four scenarios are shown in Table 3.

The experiment used a within-subject design, with each subject using both systems. In order to neutralize the effects of the individual scenarios and the order of scenarios, all subjects were presented with the same scenarios, in the same order. We alternated sessions in which the robust parser was used for scenarios one and two with sessions in which the robust parser was used for scenarios three and four. Subjects were given no prior training or warm-up exercises.

As of this writing, we have collected data from fifteen subjects. Eight of these subjects used a version of the system with the robust parser turned on for the first two scenarios and turned off for the second two; seven used the opposite configuration of full-parsing followed by robust parsing. All but two of the subjects had not used the system before.

We used our standard subject instructions, slightly modified to inform the subject that s/he would be using two distinct systems. The subjects were drawn from the same pool as in our previous data collection efforts, namely MIT students and staff. Each subject was given a $10 gift certificate for a local store. The subjects were not given any special incentive for getting correct answers, nor were they told that they would be timed. Each subject was asked to fill out a version of our debriefing questionnaire, slightly modified to include a specific question asking the subject which system s/he had preferred.

We found that writing the scenarios was tricky, and we had to iterate several times on the wording of the scenario descriptions; in particular, we found that it was difficult to elicit the desired answer. Even when we altered the instructions to remind the subjects of what
1. Find a flight from Philadelphia to Dallas that makes a stop in Atlanta. The flight should serve breakfast. Identify the type of aircraft that is used on the flight to Dallas. (Information requested: aircraft type)

2. You want to fly from Boston to San Francisco on the last weekend in April (Saturday, April 25 or Sunday, April 26). You'd like to return to Boston on the following Wednesday in the evening, if possible. Your main concern is that all flights be on Continental since you are trying to maximize your frequent flyer miles. Identify one flight in each direction (by number) that you can take. (Information requested: flight number)

3. Find a flight from Atlanta to Baltimore. The flight should be on a Boeing 757 and arrive around 7:00 P.M. Identify the flight (by number) and what meal is served on this flight. (Information requested: flight number, meal type)

4. You live in Pittsburgh. You want to combine a vacation trip to Atlanta with business and take a friend along. You will receive a fixed travel allowance, based on a first-class ticket. Identify a coach class fare (dollar amount) that comes closest to allowing you to cover the expenses of both you and your friend based on the regular first class fare. Choose a date within the next seven days and make sure the fare does not have a restriction that disallows this. (Information requested: fare amount (in dollars) for coach class fare)

Table 3: The four scenarios used by subjects in the second MIT end-to-end experiment.

Results and Analyses

From the collected data, we made a number of measurements for each scenario, and examined how the two systems differed in terms of these measures. The measurements that we computed are:

- Scenario completion time;
- Existence of a reported solution;
- Correctness of the reported solution;
- Number of queries;
- Number of queries answered; number resulting in a “no answer” message from the system;
- Logfile evaluation metrics, including queries judged to be correctly answered, incorrectly answered, partially correct, and out of domain (class X); also score, defined as % Correct - % Incorrect;
- User satisfaction from debriefing questionnaire.

Table 4 summarizes some of the results comparing the two systems across all scenarios. For the remainder of this section, we will try to analyze these results and reach some tentative conclusions.

Task Completion Time The task completion time is summarized in the third column of Table 4. The results are somewhat inconclusive, due to a number of factors. Although we were interested in assessing how long it took to solve a scenario, we did not inform our subjects of this. In part, this was because we didn’t want to add more stress to the situation. More than one subject inexplicably cleared the history after having nearly solved the scenario, and then essentially repeated, sometimes verbatim, the same series of questions. Had they thought there was a time constraint, they probably would not have done this. We suspect that because subjects were not encouraged to proceed quickly, it is difficult to draw any conclusions from the results on time-to-completion. Another insidious factor was background network traffic and machine load, factors that would contribute to variations in time-to-completion which we did not control for.
in these experiments.

The next column of the same table shows the average number of queries for each scenario. Since these numbers appear to be well correlated with task completion time, they suffer from some of the same deficiencies.

Log File Score In order to measure the number of queries correctly answered by the system, two system developers independently examined each query/answer pair and judged the answer as correct, partially correct, incorrect, or unanswered, based on the evaluation program developed for the log file evaluation. The system developers were in complete agreement 92% of the time. The cases of disagreement were examined to reach a compromise rating. This provided a quick and reasonably accurate way to assess whether the subjects received the information they asked for. The percentages of queries correctly answered, incorrectly answered, and unanswered, and the resulting DARPA score (i.e., % correct - % incorrect) are shown in the last four columns of Table 4.

Although not shown in Table 4, the overall ratio of correctly answered queries to those producing no answer was an order of magnitude higher for the robust parser (148:13) than for the non-robust parser (118:125). This was associated with an order-of-magnitude increase in the number of incorrect answers: 32 vs. 3 for the non-robust parser. However, the percentage of “no answer” queries seemed to be more critical in determining whether a subject succeeded with a scenario than the percentage of incorrect queries.

Debriefing Questionnaire Each subject received a debriefing questionnaire, which included a question asking for a comparison of the two systems used. Unfortunately, data were not obtained from the first five subjects. Of the ten subjects that responded, five preferred the robust system, one preferred the non-robust system, and the remaining ones expressed no preference.

Difficulty of Scenarios There was considerable variability among the scenarios in terms of difficulty. Scenario 4 turned out to be by far the most difficult one to solve, with only a little over half of the sessions being successfully completed. Subjects were asked to “choose a date within the next week” and to be sure that the restrictions on their fare were acceptable. We intentionally did not expand the system to understand the phrase “within the next week” to mean “no seven-day advance purchase requirement.” but instead required the user to determine that information through some other means. Also in Scenario 4, there were no available first class fares that would exactly cover two coach class fares. Scenarios 2 and 4 were intended to be more difficult than 1 and 3, and indeed they collectively had a substantially lower percentage of correct query answers than the other two scenarios, reflecting the fact that subjects were groping for ways to ask for information that the system would be able to interpret.

There was a wide variation across subjects in their ability to solve a given scenario, and in fact, subjects deviated substantially from our expectations. Several subjects did not read the instructions carefully and ignored or misinterpreted key restrictions in the scenario. For instance, one subject thought the “within the next week” requirement in Scenario 4 meant that he should return within a week of his departure. Some subjects had a weak knowledge of air travel; one subject assumed that the return trip would be on the same flight as the forward leg, an assumption which caused considerable confusion for the system.

The full parser and robust parser showed different strengths and weaknesses in specific scenarios. For example, in Scenario 3, the full parser often could not parse the expression “Boeing 757”, but the robust parser had no trouble. This accounts in part for the large “win” of the robust parser in this scenario. Conversely, in Scenario 4, the robust parser misinterpreted expressions of the type “about two hundred dollars”, treating “about two” as a time expression. This led the conversation badly astray in these cases, and perhaps accounts for the

| Scenario Number | System    | % of Scenarios w/Solution | Solution Correct | Completion Time(s) | Number of Queries | % of Queries Correct | % of Queries Incorrect | % of Queries No Answer | DARPA Score |
|-----------------|-----------|---------------------------|------------------|-------------------|------------------|----------------------|-----------------------|------------------------|-------------|
| 1               | Robust    | 100                       | 100              | 215               | 4.4              | 94                   | 0                     | 6                      | 94          |
| 1               | Full      | 86                        | 71               | 215               | 4.7              | 70                   | 0                     | 30                     | 70          |
| 2               | Robust    | 100                       | 88               | 478               | 8.6              | 66                   | 25                    | 8                      | 41          |
| 2               | Full      | 86                        | 86               | 483               | 10.6             | 39                   | 4                     | 56                     | 35          |
| 3               | Robust    | 100                       | 100              | 199               | 4.4              | 82                   | 15                    | 3                      | 68          |
| 3               | Full      | 88                        | 88               | 376               | 8.0              | 42                   | 0                     | 58                     | 42          |
| 4               | Robust    | 100                       | 71               | 719               | 11.7             | 71                   | 22                    | 6                      | 49          |
| 4               | Full      | 75                        | 38               | 643               | 9.8              | 51                   | 0                     | 49                     | 51          |
| All             | Robust    | 100                       | 90               | 389               | 7.2              | 75                   | 18                    | 6                      | 57          |
| All             | Full      | 83                        | 70               | 434               | 8.3              | 48                   | 1                     | 51                     | 47          |

*The other three scenarios were solved successfully on average nearly 90% of the time.*
fact that subjects took more time solving the scenario in robust mode. The lesson here is that different scenarios may find different holes in the systems under comparison, thus making the comparison extremely sensitive to the exact choice and wording of the scenarios.

Performance Comparison The robust parser performed better than the non-robust parser on all measures for all scenarios except in Scenario 4. In Scenario 4, the percentage of sessions resulting in a correct solution favored robust parsing by a large margin (71% vs. 38%), but the robust parser had a longer time to completion and more queries to completion than the non-robust system, as well as a worse DARPA score (51% to 49%). The robust parser gave a greater percentage of correct answers (71% vs. 51%), but its incorrect answers were significant enough (22% to 0%) to reverse the outcome for the DARPA score. Thus DARPA score seems to be correlated with time to completion, but percent of correct answers seems to be correlated with getting a correct solution.

We feel that the data for Scenario 4, when used to make comparisons between the robust and non-robust parser, are anomalous for several reasons. The scenario itself confused subjects, some of whom incorrectly assumed that the correct fare was one which was exactly one-half of the first class fare. Furthermore, fare restrictions are not as familiar to subjects as we previously assumed, leading to lengthy interactions with the system. These difficulties led to differences in performance across systems that we feel are not necessarily linked directly to the systems themselves but rather to the nature of the scenario being solved. In summary, our data show the following salient trends:

1. Subjects were always able to complete the scenario for the robust system.
2. Successful task completion distinguished the two systems: full parse system succeeded 70% of the time, compared with 90% for the robust system.
3. Percent of correctly answered queries followed the same trend as completion time and number of overall queries; these may provide a rough measure of task difficulty.
4. Scores for the performance on individual queries were not necessarily consistent with overall success in solving the problem.
5. Users expressed a preference for the robust system.

CONCLUSIONS

The results of these experiments are very encouraging. We believe that it is possible to define metrics that measure the performance of interactive systems in the context of interactive problem solving. We have had considerable success in designing end-to-end task completion tests. We have shown that it is possible to design such scenarios, that the subjects can successfully perform the designated task in most cases, and that we can define objective metrics, including time to task completion, number of queries, and number of system non-responses. In addition, these metrics appear to be correlated. To assess correctness of system response, we have shown that evaluators can produce better than 90% agreement evaluating the correctness of response based on examination of query/answer pairs from the log file. We have implemented an interactive tool to support this evaluation, and have used it in two separate experiments. Finally, we demonstrated the utility of these metrics in characterizing two systems. There was good correspondence between how effective the system was in helping the user arrive at a correct answer for a given task, and metrics such as time to task completion, number of queries, and percent of correctly answered queries (based on log file evaluation). These metrics also indicated that system behavior may not be uniform over a range of scenarios - the robust parsing system performed better on three scenarios, but had a worse DARPA score on the fourth (and probably most difficult) scenario. Based on these experiments, we believe that these metrics provide the basis for evaluating spoken language systems in a realistic interactive problem solving context.

ACKNOWLEDGEMENTS

We would like to thank several people who made significant contributions to this work. David Goodine designed and implemented the interactive log file evaluation interface which greatly facilitated running the log file evaluation experiments. Christie Winterton recruited the subjects for the various data collection experiments and served as the wizard/transcriber for many of the subjects in our end-to-end evaluation experiment. We would also like to thank Nancy Daly, James Glass, Rob Kassel and Victoria Palay for serving as evaluators in the log file evaluation.
