Tumor Promoters: Tennant’s Response

Trosko indeed presents an alternative and valid position on the nature of tumor promotion. It is certainly true that disrupted intracellular communication is an important component in the promotion and development of tumors and may be another pathway by which repetitive exposure to nongenotoxic carcinogens and genotoxic carcinogens results in altered heritable cell phenotypes. The editorial in EHP (1) was not meant to be an exhaustive catalog of all of the various mechanisms by which nongenotoxic carcinogenesis can occur. It is clear that intercellular and intracellular signaling via endocrine, exocrine, paracrine, and autocrine pathways is critical in maintaining phenotypic stability. Evidence also suggests that when gap junctional intracellular communication pathways are disrupted, the frequent consequence is altered gene expression. Preliminary experiments (2) do not suggest that exposure of skin to nongenotoxic carcinogens or to a tumor promoter results in a bewildering pattern of changes in gene expression. We believe that it is plausible that analysis of time-dependent changes in the pattern of gene expression will provide an understanding of cell-signaling pathways that are altered by chemical exposure. It may also result in the recognition of biomarkers of critical events in the neoplastic process that will include disrupted gap junctional communication.

Correction and Clarification

In the November EHPnet article “Connecting for Kids” [EHP 107:A553], we wrote of the Children’s Environmental Health Network (CEHN) “Currently, this public interest organization is lobbying the U.S. Environmental Protection Agency (EPA) to require testing of pesticides for their effects on the developing nervous systems of children.” Although the CEHN is an advocacy group, it does not lobby specific pieces of legislation. EHP regrets any confusion this wording may have caused.
