Received: September 30, 2003

Abstract. Expressions for Sudakov form factors for heavy quarks are presented. They are used to construct resummed jet rates in $e^+e^-$ annihilation. Predictions are given for production of bottom quarks at LEP and top quarks at the Linear Collider.

1 Introduction

The formation of jets is the most prominent feature of perturbative QCD in $e^+e^-$ annihilation into hadrons. Jets can be visualized as large portions of hadronic energy or, equivalently, as a set of hadrons confined to an angular region in the detector. In the past, this qualitative definition was replaced by quantitatively precise schemes to define and measure jets, such as the cone algorithms of the Weinberg–Sterman [1] type or clustering algorithms, e.g. the Jade [2] or the Durham scheme ($k_\perp$ scheme) [3]. A refinement of the latter one is provided by the Cambridge algorithm [4]. Equipped with a precise jet definition the determination of jet production cross sections and their intrinsic properties is one of the traditional tools to investigate the structure of the strong interaction and to deduce its fundamental parameters. In the past decade, precision measurements, especially in $e^+e^-$ annihilation, have established both the gauge group structure underlying QCD and the running of its coupling constant $\alpha_s$ over a wide range of scales. In a similar way, also the quark masses should vary with the scale.

A typical strategy to determine the mass of, say, the bottom-quark at the centre-of-mass (c.m.) energy of the collider is to compare the ratio of three-jet production cross sections and their intrinsic properties is one of the traditional tools to investigate the structure of the strong interaction and to deduce its fundamental parameters. In the past decade, precision measurements, especially in $e^+e^-$ annihilation, have established both the gauge group structure underlying QCD and the running of its coupling constant $\alpha_s$ over a wide range of scales. In a similar way, also the quark masses should vary with the scale.

2 Jet rates for heavy quarks

A clustering according to the relative transverse momenta has a number of properties that minimize the effect of hadronization corrections and allow an exponentiation of leading (LL) and next-to-leading logarithms (NLL) stemming from soft and collinear emission of secondary partons. Jet rates in $k_\perp$ algorithms can be expressed, up to NLL accuracy, via integrated splitting functions and Sudakov form factors [4]. For a better description of the jet properties, however, the matching with fixed order calculations is mandatory. Such a matching procedure was first defined for event shapes in [16]. Later applications include the matching of fixed-order and resummed expressions for the four-jet rate in $e^+e^-$ annihilation into massless quarks [17,18]. A similar scheme for the matching of tree-level matrix elements with resummed expressions in the framework of Monte Carlo event generators for $e^+e^-$

processes was suggested in [19] and extended to general collision types in [20].

We shall recall here the results obtained in [12] for heavy quark production in $e^+ e^-$ annihilation. In the quasicollinear limit [21,22], the squared amplitude at tree-level fulfills a factorization formula, where the splitting functions $P_{ab}$ for the branching processes $a \rightarrow b + c$, with at least one of the partons being a heavy quark, are given in $D = 4 - 2\epsilon$ dimensions by

\[
P_{QQ}(z, q) = C_F \left[ \frac{1 + z^2}{1 - z} - \frac{2z(1-z)m^2}{q^2 + (1-z)^2m^2} \right],
\]

\[
P_{gQ}(z, q) = T_R \left[ 1 - \frac{2z(1-z)}{1 - \epsilon} + \frac{2z(1-z)m^2}{(1 - \epsilon)(q^2 + m^2)} \right],
\]

where $z$ is the usual energy fraction of the branching, and $q^2$ is the space-like transverse momentum. As expected, these splitting functions match the massless splitting functions in the limit $m \rightarrow 0$ for $q^2$ fixed. Furthermore, for $q \ll (1 - z)$ $m$ the splitting function $P_{QQ}$ is not any more enhanced at $z \rightarrow 1$, which is the known “dead cone” effect. The splitting function

\[
P_{gg}(z) = C_A \left[ \frac{z}{1 - z} + \frac{1 - z}{z} + z(1-z) \right],
\]

obviously does not get mass corrections at the lowest order.

Branching probabilities are defined through [12]

\[
\Gamma_Q(Q, q, m) = \int_{q/Q}^{1-q/Q} dz \frac{q^2}{q^2 + (1-z)^2m^2} P_{QQ}(z, q)
\]

\[
\Gamma_Q(Q, q, m = 0) = C_F \left[ \frac{1}{2} - \frac{q}{m} \arctan \left( \frac{m}{q} \right) \right],
\]

\[
\Gamma_f(Q, q, m) = \int_{q/Q}^{1-q/Q} dz \frac{q^2}{q^2 + m^2} P_{gQ}(z, q)
\]

\[
\Gamma_f(Q, q, m = 0) = T_R \left[ 1 - \frac{1}{3} \frac{q^2}{q^2 + m^2} \right],
\]

\[
\Gamma_g(Q, q) = \int_{q/Q}^{1-q/Q} dz P_{gg}(z) = 2CA \left[ \ln \frac{Q}{q} - \frac{11}{12} \right]
\]

and the Sudakov form factors, which yield the probability for a parton experiencing no emission of a secondary parton between transverse momentum scales $Q$ down to $Q_0$, read

\[
\Delta_f(Q, Q_0) = \exp \left[ - \int_{Q_0}^{Q} \frac{dq}{q} \frac{\alpha_s(q)}{\pi} \Gamma_f(Q, q) \right],
\]

\[
\Delta_g(Q, Q_0) = \exp \left[ - \int_{Q_0}^{Q} \frac{dq}{q} \frac{\alpha_s(q)}{\pi} \Gamma_g(Q, q) \right],
\]

\[
\Delta_f(Q, Q_0) = \frac{[\Delta_Q(Q, Q_0)]^2}{\Delta_g(Q, Q_0)},
\]

\[
\Delta_f(Q, Q_0) = 2 \int_{Q_0}^{Q} dq \frac{\alpha_s(q)}{\pi} \Gamma_g(Q, q) \Delta_g(q, Q_0),
\]

where $Q$ is the c.m. energy of the colliding $e^+ e^-$, and $Q_0^2 = y_{\text{cut}}Q^2$ plays the role of the jet resolution scale. Single-flavour jet rates in Eq. (5) are defined from the flavour of the primary vertex.

In order to catch which kind of logarithmic corrections are resummed with these expressions it is illustrative to study the above formulae in the kinematical regime such that $Q \gg m \gg Q_0$. Expanding in powers of $\alpha_s$, jet rates can formally be expressed as

\[
\mathcal{R}_n = \delta_{n2} + \sum_{k=n-2}^{\infty} \left( \frac{\alpha_s}{\pi} \right)^k \sum_{l=0}^{2k} c_{kl}^{(n)},
\]

where the coefficients $c_{kl}^{(n)}$ are polynomials of order $l$ in $L_{yy} = \ln(1/y_{\text{cut}})$ and $L_{mm} = \ln(m^2/Q_0^2)$. The coefficients for the first order in $\alpha_s$ are given by

\[
c_{11}^{(2)} = c_{11}^{(3)} = -\frac{1}{2} C_F (L_{yy}^2 - L_{mm}^2),
\]

\[
c_{11}^{(2)} = c_{11}^{(3)} = \frac{3}{2} C_F L_{yy} + \frac{1}{2} C_F L_{mm}.
\]

The coefficients for the second order in $\alpha_s$ can be found in [12], as well as the corresponding result for the four-jet rate.

The impact of mass effects can be highlighted by two examples, namely by the effect of the bottom quark mass in $e^+ e^-$ annihilation at the $Z$-pole (Fig. 11 up), and by the effect of the top quark mass at a potential Linear Collider operating in the TeV region (Fig. 11 down). In Fig. 11 leading order (LO) and next-to-leading order (NLO) predictions for three-jet rates are compared with the NLL result as obtained by numerical integration from Eq. (4). For a comparison with the dead cone approximation see also [12]. While in the case of bottom quarks at LEP1 energies the overall effect of the quark mass is at the few-percent level, this effect becomes tremendous for top quarks at the Linear Collider. Fixed order predictions for $b$-quark production clearly fail at very low values of $y_{\text{cut}}$, by giving unphysical values for the jet rate, while the NLL predictions keep physical and have the correct shape. The latter is an indication of the necessity for performing such kind of resummations. Fixed order predictions work well for
Sudakov form factors involving heavy quarks have been employed to estimate the size of mass effects in jet rates in $e^+e^-$ annihilation into hadrons. These effects are sizeable and therefore observable in the experimentally relevant region. A preliminary comparison with fixed order results have been presented, and showed good agreement. Matching between fixed-order calculations and resummed results is in progress \[24\].
