(Dated: March 22, 2022)

We substantiate by numerical and analytical calculations that the recently discovered superconductivity below 4 K in 3% boron-doped diamond is caused by electron-phonon coupling of the same type as in MgB$_2$, albeit in 3 dimensions. Holes at the top of the zone-centered, degenerate $\sigma$-bonding valence band couple strongly to the optical bond-stretching modes. The increase from 2 to 3 dimensions reduces the mode-softening crucial for $T_c$ reaching 40 K in MgB$_2$. Even if diamond had the same bare coupling constant as MgB$_2$, which could be achieved with 10% doping, $T_c$ would only be 25 K. Superconductivity above 1 K in Si (Ge) requires hole-doping beyond 5% (10%).

PACS numbers: 74.70.-b,74.70.Ad,74.25.Kc

Recently, superconductivity below $T_c \sim 4$ K was reported in diamond doped with $\sim 3$% boron, that is, with $\sim 0.03$ holes per carbon atom [1]. Such high hole-doping levels can be achieved due to the small size of boron. It had previously been observed that the prominent Raman line caused by the zone-center optical phonons at 1332 cm$^{-1}$ downshifts and broadens significantly upon heavy boron doping [2]. In this Letter we shall make plausible that the superconductivity in hole-doped diamond is due to the coupling of the holes to the optical zone-center phonons, a mechanism similar to the one causing high-temperature superconductivity in alkali doped fullerides, and organic superconductors whose $s$-bands at the zone center. These mechanisms, a similar one causing high-temperature superconductivity in MgB$_2$, but without some of its interesting features. We shall also estimate transition temperatures for hole-doped Si and Ge.

The discovery [3] of superconductivity below 40 K in MgB$_2$, a binary compound isostructural and isoelectronic with graphite, came as a surprise for the scientific community. By now, it is well understood what the mechanism is and why MgB$_2$ is special [4,5,6,7,8]: In contrast to other known $sp^2$-bonded superconductors, such as intercalated graphite, alkali doped fullerenes, and organic superconductors whose charge carriers are exclusively $\pi$-electrons, MgB$_2$ has holes at the top of the bonding $\sigma$-bands at the zone center. These holes, on two narrow Fermi cylinders with radii $\sim 1/5$ of the Brillouin-zone radius, couple strongly ($\lambda \sim 1$) to the two optical bond-stretching modes with $q \leq 2k_F \ll k_BZ$, giving rise to a strong 2-dimensional Kohn anomaly in the phonon spectrum. This strong coupling between a few zone-center holes and optical phonons is what drives the high-temperature superconductivity in MgB$_2$. Experience shows [5], and it can be proved for parabolic bands with $2k_F \ll k_BZ$, that the coupling constant is given by the Hopfield expression,

$$\lambda = \frac{N D^2}{M \omega^2},$$

where $N$ is the density of states (DOS) per spin at the Fermi level of the $\sigma$ holes. Moreover, $\pm Du$ is the splitting of the degenerate top of the $\sigma$-band by the displacement $\epsilon\omega$ of a frozen, optical zone-center phonon with normalized eigenvector $\epsilon$ and energy $\omega$. The optical phonons are softened by the interaction with the holes, $\omega^2 \sim \omega_0^2/(1 + 2\lambda)$ when $\lambda < 2k_F$, and that significantly enhances $\lambda$ and $T_c \sim \omega \exp(-1/\lambda)$. This softening is presumably weakened by anharmonicity [9,10]. The DOS is independent of doping because the $\sigma$-band is 2-dimensional. As a consequence, a decrease in the number of holes, e.g. by carbon-doping, should not cause $\lambda$ to decrease, except through the anharmonic hardening of $\omega$ caused by the decrease of $E_F$ [11]. In stoichiometric MgB$_2$ there are more carriers in the $\pi$ bands than in the $\sigma$ bands (0.09 per B), but the former couple far less to phonons than the latter, and since there seems to be very little impurity scattering between the $\sigma$ and $\pi$ bands, MgB$_2$ is the first superconductor which clearly exhibits multiple gaps below a common $T_c$ [7,8,10,13].

Instead of having $\pi$-bands and three 2-dimensional bonding $\sigma$-bands, $sp^2$-bonded semiconductors like diamond have four 3-dimensional bonding $\sigma$-bands. The top of this valence band is three-fold degenerate with symmetry $T_{2g}$, and so are the zone-center optical phonon modes. Like in MgB$_2$, $\sigma$-holes with small $k_F$ should therefore couple strongly, and for small $k_F$ exclusively, to the optical bond-stretching modes, with the main differences being that in 3 dimensions the Kohn anomaly is weaker and the DOS increases with hole doping like $k_F$, the radius of the average Fermi sphere. Since there are 3 bands and two carbon atoms per cell, $(k_F/k_{BZ})^3 = x/3$. For $x=0.03$, $k_F/k_{BZ}$ is 0.22, which is like in MgB$_2$. Due to the lack of a metallic $\pi$-band, diamond becomes an insulator once $x$ is below 1-2 per cent. We shall now substantiate this scenario for the observed superconductivity in hole-doped diamond by providing quantitative details, and we shall also consider the possibility of superconductivity in hole-doped Si and Ge. In particular, we shall present results of density-functional (LDA) calculations and estimate $T_c$ using Eliashberg theory.

A substitutional boron impurity in diamond has an acceptor level with binding energy $0.37$ eV [14]. With increased doping, the boron impurity band will eventually overlap the diamond valence band and the system becomes metallic at a boron concentration of $8 \cdot 10^{20}$ cm$^{-3}$. Since this is one order of magnitude lower than the doping at which superconductivity was observed [1], we felt justified in using a virtual crystal
The valence bands were calculated with the scalar-relativistic full-potential LMTO method [15], and the phonon dispersions and the electron-phonon spectral function $\alpha^2 F$ were calculated with the linear-response method [15]. Effects of anharmonicity were considered in a second step. We used a triple-$k$ sp general LMTO basis set and represented the charge densities and potentials by spherical harmonics with $l \leq 6$ inside non-overlapping muffin-tin spheres and by plane waves with energies less than 400 Ry between the spheres. The resulting band structure for undoped diamond agrees with those in Fig. 1. The dispersions and the electron-phonon spectral function $\alpha^2 F$ are evaluated as a weighted sum over linewidths of individual phonons, and for this a fine, yet affordable $q$-mesh is needed. It was chosen as a $1/8^3$ sublattice in reciprocal space. The $\lambda$-values obtained are accurate when $x \gtrsim 0.05$, whereas Eq. (1) which we have now derived analytically in three dimensions, is more accurate for smaller dopings. Since, even for 10% doping, we calculated an increase of the lattice constant by less than a percent, we did use the experimental lattice parameters for the materials in all subsequent calculations.

In Fig. 1, we show the top of the valence-band structure calculated for 10% hole-doped diamond. For this unrealistically heavy doping, $N$ reaches 75% of the $\sigma$-band DOS in MgB$_2$. The electronic parameters may be found together with those for MgB$_2$ in the first columns of the table. Due to the deviations from parabolicity seen in Fig. 1, $N$ decreases somewhat faster than $x^{1/3}$. As is well known, the LDA gap is too small and this leads to a slight underestimate of the valence-band masses and the DOS. Nevertheless, properties derived from the total energy, like phonon energies, are quite accurate.

For the displacement $\epsilon_u$ of a frozen, optical zone-center phonon with two bonds stretched and two contracted, say in respectively the positive and negative $z$-directions, the top of the valence band is deformed as shown in Fig. 1. For small $k$ there are two identical bands, split in energy by $\pm Du$, and a band which does not move with respect to the Fermi level. At $\Gamma$ the corresponding wavefunctions are those linear combinations of the bond orbitals which have respectively $(p_x \pm p_y)\sqrt{2}$ and $p_z$ symmetry. The value of $D$ given in the table is seen to be nearly twice as large as in MgB$_2$. For pure diamond it agrees with the accepted value [16], and it is seen to decrease slightly with doping.

In Fig. 2 we show the phonon dispersions calculated in the harmonic approximation for undoped and hole-doped diamond. The dispersions for pure diamond, including the slight upturn of the uppermost mode when moving away from the zone center [17], are well reproduced, and for the frequency 1332 cm$^{-1}$ of the optical zone-center modes we calculate $\omega_0=1292$ cm$^{-1}$. Previous LDA calculations [18] obtained similar results. In the presence of hole-doping, the calculated dispersions of the optical modes clearly exhibit softening near the zone center and a 3-dimensional Kohn anomaly around $q=2k_F$.

The softening of the zone-center phonons is $(2/3)\lambda$ instead of $\lambda$, as in the case of MgB$_2$. This is most easily seen by considering a frozen phonon calculation and Fig. 1. The adiabatic redistribution of $(1/3)2NDu$ electrons from the upper third to the lower third of the deformed valence band decreases the energy of each electron by $Du$, and therefore perturbs the potential energy of the harmonic oscillator by $- (1/3)2ND^2u^2$. As a consequence, $(1/2)M\omega^2 = (1/2)(M\omega_0^2 - (1/3)2ND^2)$, and by use of Eq. (1) we get:

$$\omega^2 = \omega_0^2/(1 + 2\lambda/3) \quad \text{in MgB}_2.$$ \hspace{1cm} (2)

This $\omega$-value is seen to agree well with the value $\omega_{D}$ obtained by use of Eq. (1). In order to separate the materials and dimensional dependencies of $\lambda$, we express it in terms of a bare coupling constant, $\lambda_0$, and an enhancement due to the phonon softening:

$$\lambda_0 \equiv N D^2/M \omega_0^2, \quad \lambda = \frac{\lambda_0}{1 - 2\lambda_0 - \frac{2}{3} \lambda_0}. \quad \omega^2 = \frac{1}{\omega_0^2} = 1 - 2\frac{2}{3} \lambda_0. \quad (2)$$

The enhancement is weaker in 3 dimensions than in 2, where the reduction factor $2/3$ is missing. As for the materials dependence, the $\lambda_0$-values given in the table first of all show that 10% doped diamond has the same $\lambda_0 \sim 1/3$ as MgB$_2$: The bare force constant, $M\omega_0^2$, is 0.49 times its value in MgB$_2$, $N$ is 0.75, and $D$ is 1.65. Due to the difference in dimensionality, $\lambda \sim 1/3$, $N \sim 0.6$ in doped diamond, but $\lambda \sim 1/3 = 1$ in MgB$_2$. With decreasing doping in diamond, $N$ decreases roughly like $x^{1/3}$, $D$ increases slightly, and $M\omega_0^2$ is constant. As a consequence, for 3% doping $\lambda_0$ is only 0.21 and $\lambda$ is 0.30.

We can also calculate the electron-phonon spectral function and $\lambda = 2 \int \omega^{-\alpha^2 F} (\omega) \, d\omega$ numerically by sampling over all phonon branches and energy bands. The result shown in Fig. 3 confirms that only the optical phonons interact with the holes: $\alpha^2 F$ vanishes for phonon frequencies below that
of the optical zone-center modes, then jumps to a maximum, and finally falls. The decay occurs more slowly than in MgB$_2$ due to the increase of dimensionality. The $\lambda$-values ($\lambda$) obtained from this calculation agree well with those obtained from Eq. (1) and from the phonon softening.

In MgB$_2$ the role of anharmonicity of the optical phonon modes with $q < 2k_F$ has been stressed [10]: it hardens the phonon by about 20% and thus decreases $\lambda$ from 1.0 to $\lambda_\gamma$=0.78, as given in the table. However, this has recently been questioned [11]. While anharmonicity may be crucial in MgB$_2$ it has at most a noticeable effect on the superconductivity in diamond at small dopings ($x \leq 3\%$) as we shall now see: The anharmonicity appears in frozen phonon calculations (see Fig. 1), because once the displacement $u$ exceeds $E_F/D$, the lower band is full so that the screening is lost [12]. In the expression for the perturbation of the potential energy of the oscillator, $u^2$ should now be substituted by $(|u| - E_F/D)^2 \theta (E_F/D - |u|)$, provided that we simplify the DOS shape by a square. It has been shown that the most important anharmonic contribution to $T_c$ is the decrease of the first excitation energy [19]. By first-order perturbation theory, this is simply $(1/3)2N\hbar^2\pi^2 T/|\theta |(E_F/Dt)|$, where $t \equiv \sqrt{\hbar/\pi}$ is the classical turning point in the ground state. Introducing again Eq. (1) we obtain the result:

$$\lambda = \frac{\omega^2}{\omega^2_\lambda} = 1 + \frac{2}{3}\lambda \left[1 - \text{erf} (E_F/Dt)\right].$$

For MgB$_2$ the assumption of a square $N(E)$ is good, but due to the missing factor $2/3$ and the presence of the $\pi$-band, $(2/3)$ in Eq. (3) should be substituted by $[1 - N_\pi/(N + 2N_\pi)]$. For hole-doped diamond, $N(E)$ has square-root shape, and this we crudely take into account by substituting $E_F$ in Eq. (3) by $E_F' = (2/3)E_F$. In the table we have included the ratio $E_F'/D \equiv a$ as well as the results for $\lambda_a$. We see that the effect of anharmonicity may be important in MgB$_2$ but merely noticeable in hole-doped diamond [20].

For this type of superconductivity, which is characterized by an Eliashberg function with the shape exhibited in Fig. 2 and which we can idealize by a $\delta$-function at the frequency $\omega$ of the optical zone-boundary phonon, solution of the Eliashberg equations yields with high accuracy:

$$T_c = \omega \exp \left( \frac{-1}{1 + \lambda - \mu^*} \right).$$

This is McMillan’s expression with all numerical factors, which he obtained by fitting to $F(\omega)$ of niobium, set equal to unity. For the cases considered in the present paper, it does not make much difference whether one uses McMillan’s factors or unity inside the exponential, but it is important that the prefactor is $\omega$, rather than $\langle \omega \rangle/1.2$.

We can finally estimate $T_c$ from Eq. (4) with the values for $\lambda_a$ given in the table and $\omega_a$ from Eq. (5). For the Coulomb pseudopotential, the standard value $\mu^*=0.1$ was used in all cases. For MgB$_2$ we neglected the $\pi$-bands. Considering the
uncertainties in our calculation of $\lambda$ and $\omega$, the uncertainty of $\mu^*$, and the experimental estimation of the doping level, we do find critical temperatures in good agreement with present experimental knowledge. We therefore believe to have substantiated our claim that the superconductivity in hole-doped diamond is of MgB$_2$-type, but in three dimensions.

We repeated our calculations for hole-doped Si and Ge, and include those results in the table for which $E_F$ largely exceeds the spin-orbit splitting, which we neglected. Whereas hole-doped C shows superconductivity above 1 K for doping levels presently obtainable, Si and Ge seem to need twice as high doping levels. The main reason is that the deformation potential in Si and Ge is about four times smaller than in C, which is too small to take advantage of having twice as large a DOS and a three times smaller force-constant. There is also a qualitative difference to diamond: For heavily doped Si and Ge, the holes not only couple to the optical, but also to the acoustic phonons. This is the reason why $\lambda$ exceeds $\lambda_D \sim \lambda_\omega$.

In conclusion, we have shown that the recently discovered superconductivity in hole-doped diamond below 4K is of MgB$_2$-type, but in three dimensions. This means that the mechanism is coupling of a few holes at top of the $\sigma$-bonding valence band to the optical bond-stretching zone-center phonons. The increase from 2 to 3 dimensions limits the strong softening of the optical modes mainly responsible for the high $T_c$ in MgB$_2$. On the other hand, the deformation potentials in diamond are twice stronger than in MgB$_2$. Kelvin-range superconductivity in Si and Ge would require hole-doping levels of 5-10%. Finally, we have obtained simple analytical expressions for MgB$_2$-type superconductivity.

A purely electronic mechanism for the observed superconductivity was recently suggested [22], and after submission of the present manuscript two works similar to ours appeared [23] [24]. The latter used a supercell approach to simulate the boron doping and found an electron-phonon coupling in very good agreement with our results.

We are grateful to O. Dolgov, M. Cardona, G. B. Bachelet, E. Cappelluti, and L. Pietronero for many interesting discussions.
