Abstract: Methane is a vast hydrocarbon resource around the globe that has the potential to replace petroleum as a raw material and energy source. Therefore, the catalytic conversion of methane into high value-added chemicals is significantly important for the utilization of this hydrocarbon resource. However, this is a great challenge due to the high-energy input required to overcome the reaction barrier. Herein, a highly active catalytic conversion process of methane on an iron dimer anchored on a two-dimensional (2D) C$_2$N monolayer (Fe$_2$@C$_2$N) is reported. Density functional theory calculations reveal that the superior properties of Fe$_2$@C$_2$N can be attributed to the formation of the Fe-O-Fe intermediate with H$_2$O$_2$ as the O-donor molecule, which facilitates the formation of methyl radicals and promotes the conversion of methane. This finding could pave the way toward highly efficient non-precious metal catalysts for methane oxidation reactions.

Keywords: non-precious metal catalysts; Fe$_2$ dimer; C$_2$N monolayer; density functional theory; Fe-O-Fe intermediate; methane conversion

1. Introduction

Energy sources have become a major worldwide concern in recent years, as a result of global climate crisis and reduced fossil fuel reserves. China has relatively large reserves of natural gas and shale gas. The main component of natural gas is methane, which is a high-quality and clean energy source, abundant in nature, thus making natural gas an appealing feedstock for making valuable chemicals and fuels [1–3]. Today, with the depletion of petroleum resources, effective development and utilization of natural gas has attracted substantial interest from academia and industry. Unfortunately, most methane is distributed in remote and sparsely populated areas, which makes the transportation of methane over long distances energy-intensive and costly [4]. Therefore, there is a high demand for methods to convert methane into more transportable and high value-added chemicals.

Methane is the most stable hydrocarbon, with a tetrahedral geometry of four equivalent C–H bonds, where the carbon atom is located in the center of the regular tetrahedron in a sp$^3$ hybridization with a C–H bond length of 1.09 Å and a H–C–H bond angle is 109.5°. The large bond dissociation energy of the methane molecule (435 kJ·mol$^{-1}$) hinders the cleavage of the C–H bond [5], which means that methane conversion usually requires high temperatures to overcome the high reaction barrier. Such high temperatures are not conducive to industrial application. Although long-term efforts have been devoted to studying the “Holy Grail” of catalysis [6], i.e., the direct conversion of methane into methanol, formaldehyde, etc., the yield and selectivity of these reactions are low. Up till now, it is not able to compete with traditional petrochemical processes, making it difficult to achieve its industrialization in the short term. Therefore, over the past few decades many experimental and theoretical investigations have focused on developing catalysts to achieve high methane conversion rates under mild conditions [7–9]. It has been reported both experimentally and theoretically
that [10–13] reducing the size of supported metal nanoparticles can enhance the catalytic efficiency. A heterogeneous catalytic process would be the preferred scheme for the low temperature methane oxidative conversion [14].

Due to the unique structure of two-dimensional (2D) materials, single atom embedded 2D materials offer an opportunity to significantly enhance catalytic activity. Sanjubala et al. [15] investigated the use of free and graphene-supported single transition metal Cr, Mn, Fe, Co and Cu atoms for the activation of methane, and found that Co atoms supported on graphene could be a very effective catalyst for methane activation. Yuan et al. [2] demonstrated a two-step reaction mechanism for the direct oxidation of methane to methanol over a single atom Co-embedded graphene catalyst by using first principle calculations, with N₂O as the O-donor, and they predicted that the catalyst would be highly reactive and selective under mild conditions. Interestingly, the enzyme methane monoxygenase is capable of selectively oxidizing methane to methanol at room temperature, and the active site for this enzymatic system consists mostly of iron and copper [16–19]. Although such biocatalysts are difficult to scale-up, the nature of their active sites provides inspiration for the development of highly active catalysts. Some of the most efficient catalysts for activating methane under mild conditions are iron-exchanged zeolites, as they have active centers similar to that of methane monoxygenase [20,21]. In particular, iron-embedded graphene exhibits good catalytic activity for N₂O decomposition, since the involved activation energy is only 8 kcal mol⁻¹ [22]. Based on this finding, Impeng et al. [7] recently showed that FeO/graphene provides excellent reactivity for the oxy-functional oxidation of methane to methanol.

In addition to graphene, they also found that the methane C-H bond cleavage is favorable on the Fe/boron nitride (BN) system with a lower energy barrier of 10 kcal mol⁻¹ [14]. Cui et al. demonstrated that graphene-confined single Fe atoms can be used as an efficient metal catalyst to directly convert methane at room temperature, with a low rate-determining (C–H bond cleavage) reaction energy barrier of 0.79 eV [9]. That is, we can choose suitable supports to properly design catalysts with high activity. As an extension of these single atom catalysts, diatomic catalysts, which feature larger adsorption sites and modes, have been widely studied [23–27], and are thus conducive to improving the catalytic activity of metal atoms or providing other reaction pathways.

A novel carbon-nitrogen porous 2D C₂N crystal compound, which was successfully prepared by a simple bottom-up wet chemical reaction method [28], has also attracted the interest of researchers [29–31]. With big pores, C₂N can tightly anchor one or two metal atoms, whereby the lone pairs of electrons of the sp² hybridized nitrogen atoms at the edge of the pores can strongly couple with the metal atoms, thereby preventing their mobility and providing a good coordination site for the metal single atom and clusters. A high surface-to-volume ratio ensures that the metal atoms can be sufficiently exposed to the substrate, which facilitates adsorption of reactant molecules and promotes catalytic reactions. For example, the diatomic catalysts Cu₂@C₂N and Fe₁Cu₁@C₂N were found to possess better catalytic performance for CO oxidation than SAC Cu₄@C₂N does [22,24]. Compared with a single Fe atom, the Fe₂ dimer provides larger adsorption sites, thus we expect that the Fe₂ dimer supported on the 2D C₂N monolayer (Fe₂@C₂N) will possesses good catalytic performance for methane conversion. A recent work by Zhao et al. found that Fe₂@C₂N has remarkable selectivity for C₂H₅OH against other C₁ and C₂ products on CO₂ reduction [32]. In this work, we explore the potential of the Fe₂@C₂N as an efficient catalyst to catalyze the methane conversion reaction by means of periodic density functional theory (DFT) calculations. Our results indicate that the Fe₂ dimer embedded in the C₂N monolayer is a promising catalyst for methane conversion, whose activation barrier for the C-H breakage (0.66 eV) is estimated to be comparable to or lower than those of reported Fe-based catalysts (0.52 – 0.79 eV) [8,33,34]. This work should be helpful to provide guidelines for experimentalists to design low-cost and effective catalysts for methane conversion.
2. Results and Discussion

Methane activation on 2D C\textsubscript{2}N embedded Fe\textsubscript{2} dimer was studied by means of DFT computations. We found that the methane first generates methyl radicals, which subsequently turn into value-added C\textsubscript{1} oxygenated products. As a result, the methane C–H bond cleavage is both kinetically and thermodynamically favorable.

2.1. Geometric Structure and Electronic Properties of the Fe\textsubscript{2}@C\textsubscript{2}N Monolayer

Firstly the geometric and electronic properties of Fe\textsubscript{2} clusters on the C\textsubscript{2}N monolayer were investigated. According to a previous study [35], there are two configurations for the TM\textsubscript{2}@C\textsubscript{2}N, in which both two metal atoms coordinate with two N atoms or three N atoms of the C\textsubscript{2}N substrate, respectively. Herein, the coordination of Fe atoms with three N atoms is more stable (Figure 1a), the distances of Fe-N bonds are in the range of 1.93 ~ 2.43 Å, and the Fe\textsubscript{2}@C\textsubscript{2}N monolayer displays a slightly distorted plane, with the two Fe atoms above and below the plane. The large binding energy between the Fe atom and C\textsubscript{2}N (the binding energy of each Fe atom is 4.30 eV) implies that the Fe\textsubscript{2} dimer could bond strongly with C\textsubscript{2}N, suggesting good stability. Previous \textit{ab initio} molecular dynamics (AIMD) simulation results [35] have also shown that the Fe\textsubscript{2}@C\textsubscript{2}N structure has good thermodynamic stability. The electrical conductivity is an important indicator to evaluate the catalyst activity. Therefore, the band structures of Fe\textsubscript{2}@C\textsubscript{2}N, which exhibits metallic properties, were computed (Figure 1b). The electronic structures reflected by the partial density of states (PDOS) show that electronic coupling mainly originates from the Fe-3\textit{d} and N-2\textit{p} orbitals (Figure 1c). The Bader charge analysis showed that each Fe atom extracts 0.74 e from the C\textsubscript{2}N, indicating its high activity.

(a) Top and side view of the structure of Fe\textsubscript{2}@C\textsubscript{2}N in a 2 \times 2 \times 1 supercell; (b) Band structure; (c,d) Projected density of state (PDOS) of the Fe\textsubscript{2}@C\textsubscript{2}N and Fe-O-Fe@C\textsubscript{2}N intermediate. The Fermi level is set to zero.](image)

2.2. Methane Activation over the Fe\textsubscript{2}@C\textsubscript{2}N Monolayer

We first examined the adsorption of the oxidant H\textsubscript{2}O\textsubscript{2} on the Fe\textsubscript{2}@C\textsubscript{2}N, and we found that the H\textsubscript{2}O\textsubscript{2} dissociates (*H\textsubscript{2}O\textsubscript{2} → *H\textsubscript{2}O + *O) spontaneously. The potential energy profile of H\textsubscript{2}O\textsubscript{2} dissociation catalyzed by Fe\textsubscript{2}@C\textsubscript{2}N (Figure 2) is highly exothermic (~4.17 eV), revealing that the Fe\textsubscript{2}@C\textsubscript{2}N is an efficient catalyst for H\textsubscript{2}O\textsubscript{2} decomposition. The H\textsubscript{2}O desorption from Fe\textsubscript{2}@C\textsubscript{2}N is very easily due to the very small adsorption energy of ~0.23 eV. After the removal of the H\textsubscript{2}O molecule, the Fe-O-Fe intermediate was formed, where the two Fe-O bond lengths are both 1.80 Å, and the Fe-N bonds changed to 1.89 ~ 2.05 Å, while the C-N distances remain the same as those of the pristine Fe\textsubscript{2}@C\textsubscript{2}N. The electronic state of the Fe-O-Fe intermediate near the Fermi level is increased compared to the original Fe\textsubscript{2}@C\textsubscript{2}N (Figure 1c,d), leading to the Fe-O-Fe intermediate being more active, serving as the active site in all the subsequent oxidation reactions. The main reaction pathway of methane oxidation process as is shown in Figure 3. Below we will discuss the complete oxidation process.
Figure 2. Transformation process of a Fe2 dimer in H2O2 solution. The inset was the atomic structure model of each step.

Figure 3. The possible reaction pathways for methane oxidation processes.

The calculated potential energy profile for methane conversion on the Fe-O-Fe active sites generated on Fe2@C2N by decomposition of H2O2 is illustrated in Figure 4 (the optimized geometries of intermediates in the reaction are given in the insets). The first elementary reaction starts with the adsorption of the methane on the Fe-O-Fe intermediate via van der Waals interactions, where one hydrogen atoms pointing towards the oxygen atom with a distance of about 2.29 Å and an adsorption energy of −0.58 eV. The C–H bond activation begins to transfer one H atom from C atom of methane to O atom coordinated to the Fe2 dimer, leading to the formation of the methyl species and the hydroxyl group, where the activated C–H bond of methane is elongated from 1.10 to 1.48 Å, and the formed O-H bond is 0.98 Å (the original distance is ~2.29 Å). This step is endothermic by 0.36 eV. After the first C-H bond of methane is broken, the Fe-O-Fe active site continues to sequentially activate other C-H bonds, generating a series of oxidation products. The formed methyl radical has two different ways to proceed: (1) It can combine with the *OH to form a C-O bond (the C-O bond length is 1.45 Å), leading to the formation of CH3OH adsorbed on the Fe2 active center, and the Fe-O distance in the CH3OH adsorption complex is 2.20 Å (the red line in Figure 4). (2) Or it can react with *OOH in the H2O2 solution to form CH3OOH, where the C-O bond length is 1.40 Å (the blue line in Figure 4). It is worth noting that whether the methyl radical forms a CH3OH or CH3OOH, both processes are exothermic, by −0.52 and −0.65 eV, respectively. The adsorption energies of *CH3OH or *CH3OOH are −0.45 and −0.18 eV, respectively. After the removal of *CH3OOH, the geometrical structure of the Fe2 dimer will recover to the original Fe2@C2N structure. Subsequently, the Fe2@C2N monolayer will react with further H2O2 in the solution to cycle back to the Fe-O-Fe active structure, and thus continue to convert CH3OH into other chemicals. The formed Fe-O-Fe intermediate will interact with the H atom bonded with the C atom in CH3OH to form *OH (the O-H bond length is 1.11 Å) and •CH3OH. Similar to the case of the methyl radical, CH2OH can also react either with *OH to form HOCH2OH (the red line in Figure 4), or with *OOH in the solution to form HOCH2OOH (the blue line in Figure 4), and the two steps are exothermic by −0.48 and −1.26 eV, respectively. The formed HOCH2OH will dehydrate to form HCHO with the reaction energy of 0.65 eV. The Fe-O-Fe intermediate will continue to extract one H in HCHO to form *OH and •CHO, a step that is exothermic by −0.20 eV. Finally, the •CHO and *OH combine to form HCOOH product, which releases an energy of −1.13 eV. As a result, the conversion of methane on the Fe2@C2N is exothermic by −5.24 eV for the overall steps, (the red lines in Figure 4), and the rate-determining step is the dehydration of HOCH2OH, which consumes the energy of 0.65 eV.
1.80 Å, is comparable to the reported Fe–O bond lengths in the zeolite and in the enzyme [37,38].

The calculated adsorption energy of methane (−0.58 eV) is comparable with the methane on Fe-GP (about −0.50 eV) and Fe-BN (about −0.62 eV) [14]. The most important point of the reaction pathway is the methane activation on the Fe-O-Fe species, and the reaction energy for this step is endothermic by 0.36 eV, which is much lower than the energy on traditional effective catalysts, such as CoO/Gr (0.56 eV), FeO/Gr (~0.70 eV) [2,7]. By calculating the formation energy of hydrogen, we estimate that the methane activation energy barrier is about 0.66 eV, which is comparable to that determined for Fe-exchanged zeolites (0.52 eV and 0.69 eV) [33,34]. More importantly, it is smaller than the energy barrier on O-FeN4-O in graphene (0.79 eV), which agrees with our conjecture that Fe2@C2N is a promising catalyst for CH4 conversion. Moreover, the recycling ability is major demand in developing suitable catalysts for the conversion of methane. The Fe2@C2N almost remains in the original structure throughout the reaction and the catalytically active center Fe-O-Fe can be regenerated by introduction of H2O2. From the computed free energies of the reaction pathways, we conclude that the reaction mechanism is that the methyl radical is first converted to CH3OH and CH3OOH, the CH3OH can be further converted to HOC(H)OOH and HCOOH. The features of the energy diagrams are similar to those on the O-FeN4-O structure [9], and the overall reaction is exothermic by −5.24 eV. Furthermore, compared with the core steps of methane conversion in the graphene-confined single iron atom, the Fe2@C2N exhibits even higher catalytic activity: the key step of C–H cleavage is endothermic by 0.36 vs. −0.45 eV [9]. Synder et al. [39] reported that the high O-H formation energy (ΔE(O-H)) will highly activate the abstraction of H-atom of methane. Therefore, we calculated ΔE(O-H) on the Fe-O-Fe intermediate (~4.81 eV), which is close to the value of the best represents active site [FeO]2+ reported in Fe-zeolites (~4.42 eV) [39], suggesting that the Fe-O-Fe intermediate shows good activity for the C-H activation.

3. Materials and Methods

Spin-polarized density functional theory (DFT) calculations were carried out with the Vienna ab initio simulation package (VASP) [40] using the projector augmented wave (PAW) method [41]. The generalized gradient approximation (GGA) with the Perdew-Burke-Ernzerhof (PBE) exchange-correlation functional was adopted [42]. The energy cutoff for the plane-wave basis set was chosen as 550 eV, the systemic energy tolerance and the remaining total force were set as 1 × 10−5 eV and 0.01 eV Å−1, respectively.
The Brillouin zone was sampled with a $5 \times 5 \times 1$ k-mesh of the Monkhorst-Pack scheme [43] for geometry optimization, and a denser k-mesh of $15 \times 15 \times 1$ for electronic structure computations.

The lattice parameter of the 2D C$_2$N monolayer was calculated to be $a = b = 8.32$ Å, which was consistent with the experiment reports [28]. A C$_2$N supercell with $2 \times 2 \times 1$ unit cells, containing 48 C atoms and 28 N atoms, was used in this work (Figure 5a). The computed energy band gap of C$_2$N monolayer (Figure 5b,c) is 1.66 eV, which is consistent with previous reports [30]. The periodic boundary condition was set with a 20 Å vacuum region above the plane of one C$_2$N unit cell, which was large enough to avoid interaction from the neighboring images. The reaction energy of elementary catalyst and the adsorbate, the pristine Fe$_2$@C$_2$N, and the isolated adsorbate, respectively. According to this definition, a more negative value of $E_b$ means better thermodynamic stability.

The adsorption energy ($E_{ads}$) of the adsorbates was computed according to the following equation:

$$E_{ads} = E_{tot} - E_{Fe2@C2N} - E_{adsorbate}$$

(2)

where the $E_{tot}$, $E_{Fe2@C2N}$ and $E_{adsorbate}$ represent the total energies of the system containing the Fe$_2$@C$_2$N catalyst and the adsorbate, the pristine Fe$_2$@C$_2$N, and the isolated adsorbate, respectively. According to this definition, a more negative value of $E_{ads}$ means better thermodynamic stability.

The descriptor $E_H$ proposed by Latimer et al. [44,45] can accurately estimate the methane transition state (TS) energy, while avoiding the tedious transition state energy calculation, and the error of this descriptor is comparable to the typical accuracy of DFT adsorption energy. Therefore, in this work, we used this descriptor to quickly estimate the activation energy of the methane C–H bond:

$$E_{TS} = 0.75 E_H + 1.09$$

(3)

where $E_{TS}$ and $E_H$ represent the energy of the methane TS energy and the affinity of hydrogen, respectively.

The formation energy of O–H bond was computed according to the following equation:

$$\Delta E_{O-H} = E_{OH^*} - E_{H^*} - 0.5 E_{H2}$$

(4)
where the $E_{\text{OH}^*}$, $E_{\text{H}^*}$ are the total energies of O* and OH* adsorbed on the pristine Fe$_2$@C$_2$N, respectively. The calculation of H$_2$ was to place it in a 15 × 15 × 15 cubic cell, using Gamma point only.

4. Conclusions

In this work, the direct conversion of methane over a Fe$_2$@C$_2$N monolayer, with H$_2$O$_2$ as the oxidant, was investigated by means of density functional theory calculations. Our calculations revealed that the Fe$_2$@C$_2$N is a highly efficient catalyst for methane activation, and the high activity is mainly due to the formation of Fe-O-Fe intermediates. Because of a strong formation energy of the O-H bond on the Fe-O-Fe intermediate, methane activation is driven to proceed with a low energy barrier. Based on the proposal of synthesizing Cu$_2$@C$_2$N [23], it is feasible to obtain Fe$_2$@C$_2$N by using FeCl$_2$ and other proper metal precursors. Hopefully, our theoretical study may pave the way toward the design of highly efficient C$_2$N-supported non-precious catalysts for the conversion of methane to high value-added chemicals. One should note that the support, coordination and electronic effects impact the activity and selectivity of the supported dimer catalysts [27], so other metal dimers may also have good catalytic performance for methane conversion [46].
