Abstract—To clarify the histamine (HA) dynamics in peripheral tissues, effects of drugs on the tissue HA and tele-methylhistamine (t-MH) levels were studied in mice. α-Fluoromethylhistidine (50 mg/kg, i.p.) significantly decreased the HA level in the stomach, but not in the liver, heart, ileum, submandibular gland and skin of mice. This compound had no significant effect on the t-MH level in any tissue examined. In non-fasted and 24-hr fasted animals, the t-MH level in the liver, heart and ileum was significantly increased by treatment with aminoguanidine (10 mg/kg, i.p.) plus pargyline (65 mg/kg, i.p.). However, in mice fasted for 48 hr, this treatment was ineffective in increasing the t-MH level in the heart and ileum, suggesting that the t-MH level in some peripheral tissues is under the influence of the food intake. Even if HA is synthetized and then metabolized in the peripheral tissues, the size of the HA pool with a rapid turnover in each tissue except for the gastric tissue seems to be very small.

Histamine (HA) is present in almost all mammalian tissues. In general, the skin, lung and gastrointestinal tract are rich sources of HA (1, 2). It has been established that HA plays roles in anaphylaxis, acute inflammation and gastric secretion. However, the physiological roles of HA in most peripheral tissues are poorly understood.

Except for the brain (3–7) and stomach (4, 8, 9), a large majority of HA contained in most tissues appears to undergo a very slow turnover. However, Levine et al. (10) suggested the presence of a HA pool with a rapid turnover in the rat heart, and Håkanson et al. (11) suggested the presence of neuronal HA in the intestinal wall, which likewise may undergo a rapid turnover.

HA is synthetized from L-histidine by histidine decarboxylase and is metabolized through two pathways, i.e., oxidative deamination by diamine oxidase (DAO) to imidazoleacetic acid and methylation by HA-N-methyltransferase to tele-methylhistamine (t-MH) (12). t-MH undergoes oxidative deamination to tele-methylimidazoleacetic acid. In peripheral tissues, both DAO and monoamine oxidase (MAO) seem to be involved in this process (13, 14).

(S)-α-Fluoromethylhistidine (α-FMH) is a specific inhibitor of histidine decarboxylase (15). Aminoguanidine (16) and pargyline are inhibitors of DAO and MAO, respectively. Thus, information on the dynamics of endogenous HA in peripheral tissues may be obtained from the decrease in the tissue HA level induced by α-FMH and the increase in the t-MH level induced by the combination of aminoguanidine and pargyline. α-FMH and pargyline proved to be valuable tools for investigating the HA dynamics in the mammalian brain which lacks DAO (3, 4, 6, 7).

In an attempt to obtain further knowledge of the dynamics of HA and t-MH in the peripheral tissues, we used high performance liquid chromatography with fluorescence detection for the determination of the levels of amines in several peripheral tissues of mice given various treatments. This method for simultaneous determination of HA and t-MH was developed by Tsuruta et al. (17).
Materials and Methods

Chemicals and drugs: All chemicals used were at least of a guaranteed reagent grade. HA dihydrochloride was obtained from Wako Chemicals (Osaka, Japan); t-MH dihydrochloride and pros-methylhistamine dihydrochloride from Calbiochem-Behring Corp. (San Diego, CA, U.S.A.); aminoguanidine bicarbonate from Nakarai Chemicals (Kyoto, Japan); and pargyline hydrochloride from Sigma Chemical Co. (St. Louis, MO, U.S.A.). a-FMH hydrochloride was a generous gift from Dr. J. Kollonitsch of Merck Sharp & Dohme Research Laboratories (Rahway, NJ, U.S.A.).

Animals: Male ddY mice weighing 25–30 g (Shizuoka Laboratory Animal Center, Hamamatsu, Japan) were housed in groups in a room controlled at 22±2°C. Food and water were provided ad libitum. When fasted, the animals were placed in cages for 24 or 48 hr before killing, with access only to water. Aminoguanidine, pargyline and a-FMH were dissolved in 0.9% saline and injected i.p. in doses of 10 mg free base/kg, 65 mg free base/kg, and 50 mg free base/kg, respectively. a-FMH was injected 12 hr before and aminoguanidine and pargyline were injected 4 hr before the mice were killed. When the effect of orally administered HA was studied, HA dissolved in saline was given in a dose of 10 mg free base/animal, using a stomach cannula.

Determination of HA and t-MH: Mice were killed by cervical dislocation, the tissues (liver, heart, ileum, stomach, skin and submandibular gland) immediately removed, washed in cold saline, weighed and homogenized in 10 ml of 0.4 N perchloric acid with an appropriate amount (15 ng–2 μg) of pros-methylhistamine as the internal standard. The homogenate was frozen and stored at -20°C until assay. The HA and t-MH were simultaneously determined by a slight modification (18) of the procedure of Tsuruta et al. (17). The high performance liquid chromatography system was composed of a LC-3A pump (Shimadzu, Kyoto, Japan), a RF-530 fluorescence spectromonitor (Shimadzu) and a reverse-phase column (150×4.0 mm inside diameter) packed with Chemcosorb ODS-H (5 μm, spherical form; Chemco Scientific Co., Osaka, Japan).

Statistical analysis: The data were evaluated for statistical significance by Student’s t-test.

Results

Effects of a-FMH on the tissue HA and t-MH levels: The HA level in the stomach of 12-hr fasted mice significantly decreased 12 hr after a-FMH treatment, as compared with the saline-treated control group (Fig. 1). However, no significant changes in the HA level were observed in the liver, ileum, heart, submandibular gland and skin. a-FMH had no significant effect on the t-MH level in any tissue examined.

Effects of aminoguanidine and pargyline on the tissue HA and t-MH levels: When the effects of aminoguanidine and pargyline on the tissue HA and t-MH levels were studied...
in mice fasted for 24 hr, no changes in the HA level were produced by aminoguanidine and pargyline administered either separately or together (Table 1). However, the t-MH level in the liver, heart and ileum was significantly increased by the combined treatment with these drugs. Aminoguanidine administered alone significantly increased the t-MH level in the liver.

**Effects of fasting on the steady-state tissue levels of HA and t-MH and the changes in these amine levels induced by aminoguanidine and pargyline:** The gastric HA level in mice fasted for 48 hr was sig-

significantly higher than the level in non-fasted mice (Table 2). However, fasting had no significant influence on the HA level in other tissues studied. The t-MH level in the liver, heart and ileum was significantly increased by fasting.

In non-fasted mice, the t-MH level in the liver, heart and ileum was significantly increased by the treatment with amino guanidine plus pargyline. Similar effects of the combined treatment with these drugs on the t-MH level in these tissues were observed in mice fasted for 24 hr (Table 1). However, in mice fasted for 48 hr, a significant increase in the t-MH level was observed only in the liver, after the same treatment.

In 48-hr fasted mice treated with amino guanidine plus pargyline, both HA and t-MH levels in the ileum were markedly lower than the values in non-fasted mice given the same combined treatment.

Effects of the oral administration of HA on the tissue HA and t-MH levels: This experiment was designed to determine whether dietary HA at least in part can escape metabolic changes and reach peripheral tissues. When mice were given orally 10 mg/animal of HA 3 hr before killing, the HA and t-MH levels in the liver, heart and stomach significantly increased (Table 3). The increases in these amine levels were far more marked in mice pretreated 4 hr before killing with aminoguanidine plus pargyline than in the saline-pretreated mice, except for the HA level in the stomach.

Discussion

The t-MH level in the mouse stomach determined in the present study was in a range of the values obtained by Imamura et al. (19) who used the dansylation method.

In the present experiment, α-FMH decreased the gastric HA level in 12-hr fasted mice by 53.3% 12 hr after treatment. This is in good agreement with the result of Maeyama et al. (4). However, Bouclier et al. (9) reported that α-FMH caused no change in the gastric HA level throughout the 24-hr period after treatment in fasted pylorus-ligated rats. Such discrepancies may not be due to species differences but to the difference in HA turnover in the stomach between fed and fasted animals. This view is supported by the observation that α-FMH was much less effective in decreasing the gastric HA level in fasted than in fed mice (data not shown).

In 48-hr fasted mice treated with aminoguanidine plus pargyline, both HA and t-MH levels in the ileum were markedly lower than the values in non-fasted mice given the same combined treatment.

re-feeding results in the release of mucosal HA accumulated during fasting and there is a subsequent elevation of histidine decarboxylase activity.

α-FMH did not decrease the HA level in the liver, heart, ileum, skin and submandibular gland, thereby suggesting that if such exists, the size of a rapidly turning over pool(s) for endogenous HA in these tissues is very small. However, Levine et al. (10) reported that histidine decarboxylase inhibitors, such as α-hydrizinohistidine and NSD-1055 (brocresine) caused a significant decrease in the cardiac HA level in rats. α-FMH is a more potent and specific inhibitor of histidine decarboxylase than α-hydrizinohistidine and NSD-1055 (15, 20). The reason for the discrepancy between our result and that of Levine et al. (10) is not clear.

In the present experimental conditions, α-FMH had no significant influence on the t-MH level in any of the peripheral tissues studied. Therefore, it is likely that the maintenance of the steady-state t-MH level in these tissues does not largely depend on methylation of the HA from a pool(s) with a rapid turnover present in the respective tissues, at least under the conditions studied. The observations made in the peripheral tissues are in contrast with the α-FMH-induced decrease in the t-MH level in the brain (6, 7). t-MH formation from L-3-methylhistidine by histidine decarboxylase has been noted in several mouse tissues (21). However, since α-FMH did not decrease the t-MH level in all the tissues studied, the contribution of this pathway may also be small in maintaining the t-MH level.

In the present experimental conditions, the combined treatment with aminoguanidine and pargyline significantly increased the t-MH level in the liver, heart and ileum of non-fasted and 24-hr fasted mice. No significant drug-induced increase in the t-MH level was observed in the stomach, skin and submandibular gland. This may be due to a much higher steady-state t-MH level in these tissues than in the liver, heart and ileum. The combined treatment with aminoguanidine and pargyline was ineffective in elevating the t-MH level in the heart and ileum of mice fasted for 48 hr. Therefore, the t-MH level in these tissues seems to be under the influence of the supply of HA and/or t-MH from the blood, and food seems to be an important source of these blood amines. Especially in the ileum of 48-hr fasted mice, the HA level was lower than the level in non-fasted mice, the difference being significant in the group treated with aminoguanidine plus pargyline. When treated in the same way, the t-MH level in the ileum of 48-hr fasted mice was significantly lower than the corresponding value in non-fasted mice. This suggests that HA in food is absorbed from the intestines and partly metabolized by DAO and MAO in these tissues. However, the reason for the significantly higher t-MH values in 48-hr fasted mice treated with saline is unknown. Besides, the endogenous HA released from the gastric tissue in response to the food intake may also contribute to the increase in the tissue t-MH level in mice receiving the above drug treatment. Mice fed a HA-free food may be useful to estimate the contribution of endogenous HA to the maintenance of the tissue t-MH level and the drug-induced increase in this amine level.

The HA and t-MH levels in the liver, heart and stomach markedly increased after the oral administration of HA. Although the dose used was unphysiologically high, this finding suggests that HA contained in food can be absorbed from the gastrointestinal tract and transported to other peripheral tissues in the form of HA and/or t-MH.

In conclusion, the present results suggest that the HA pool with a rapid turnover in the tissues examined except for the stomach is extremely small, if such exists, and that the t-MH level in some peripheral tissues of mice is influenced by the food intake.
