(Dated: May 19, 2020)

We consider the thermal conductivity, shear viscosity, and momentum relaxation rates in the nucleon cores of the neutron stars. We study how the choice of the nuclear interaction and the model for three-body forces may affect these transport coefficients calculated within the Brueckner-Hartree-Fock many-body nuclear theory. We find that at relatively large densities the model dependence of the results is substantial. In addition we provide the analytical approximations which allow to incorporate our results in practical simulations.

I. INTRODUCTION

Studies of matter at and beyond the nuclear density ($n_0 \approx 0.16$ fm$^{-3}$) attract constant interest as a way to test fundamental physical theories such as theories of strong interactions. One of a few ways to study matter at supranuclear densities comes from the neutron star astrophysics. Neutron stars (NSs), having masses of the order of the Solar mass $M_\odot$ and radii of the order of tens of kilometers, are largely composed of the superdense matter in their liquid cores, although the exact composition and equation of state (EOS) of this matter are unknown [1]. In particular, the properties of the superdense matter inside NS cores affect the flow of various non-equilibrium processes that have observational consequences. Confronting the results of modeling of such processes with the astrophysical observations potentially allows one to infer the underlying physical properties deep in NS interiors. The important microphysical input to such a modelling are the transport properties of the NS matter.

Transport properties of NS interiors were studied intensively in the last decades, see Ref. [2] for a review. Most of the results were obtained for a simplest nucleon composition of NS cores, where the matter constituents are neutrons (n), protons (p), electrons (e), and muons (µ). The matter inside NSs is thought to be at, or close to the equilibrium with respect to the weak reactions, the so-called beta-stable matter. In this case the proton (and lepton) fraction $x_p$ is small, $x_p \lesssim 0.2 - 0.3$ [1]. Depending on the transport problem considered, the largest contribution to transport coefficients comes from neutrons or leptons, with the protons giving the least important contribution. The first detailed studies of the diffusive transport coefficients of NS cores were performed by Flowers and Itoh [3]. Their consideration of nucleon transport coefficients was based on the free-space scattering cross-sections. However, since nucleons inside NS cores form dense non-ideal strongly interacting Fermi liquid, the appropriate nuclear many-body theory needs to be incorporated. The approaches to this problem included the in-medium perturbation theory based on the Brueckner G-matrix [17] or thermodynamical T-matrix [5], variational approach within the correlated basis function formalism [4] [9][10], and the medium-modified one-pion exchange model [11][12] in the framework of Landau-Migdal Fermi-liquid theory [13], see Ref. [2] for the more detailed review.

In the present study we continue our previous work [6] and investigate the the transport coefficients of the NS cores within the Brueckner-Hartree-Fock (BHF) framework. We limit ourselves to the simplest npeµ composition of the NS cores and focus on the nucleon contribution to the transport. For the up-to-date results on the lepton contribution, see Refs. [2] [14][17]. Previously [6] we obtained the nucleon thermal conductivity $\kappa$ and shear viscosity $\eta$ within this model in the beta-stable matter of NS core for one particular nuclear interaction, namely the Argonne v18 potential supplemented with the Urbana IX three-body force. Here we explore the dependence of our results on the choice of the nuclear potential following Ref. [18] where similar analysis was performed for the nucleon effective masses. In addition, we also consider the momentum relaxation rate in the neutron-proton collisions, an important transport coefficient in studies of the magnetic field evolution in NS cores [2] [19][21].

Preliminary results of the present studies were reported in Ref. [7]. We find, that the dependence of the transport coefficients on the model of the potential can be substantial at high baryon densities. The main difference seems to come from the model for three-body forces. While at low densities, $n_B \sim n_0$, all calculations agree, at higher densities values of thermal conductivity, shear viscosity, and momentum relaxation rate can differ by an order of magnitude depending on the selected NN interaction.

The paper is organized as follows. In Section [11] we outline the formalism used to calculate the kinetic coefficients and introduce the effective mean free paths of the transport theory. In Section [11] we shortly review the
BHF approach and we present our results in Section IV. In Section IV A we analyse the dependence of the effective mean free paths on the selection of the nuclear potential. In Section IV B we discuss the simplifications that can be used in calculation of the shear viscosity and thermal conductivity. In Section IV C we try to isolate main partial waves of the nucleon interaction that are responsible for the difference in the results. Finally in Section IV D we provide the practical expressions for calculating the transport coefficients in our model. We conclude in Section IV.

In what follows, we set $\hbar = k_B = c = 1$, except for the practical expressions in Section IV D. Effects of nucleon pairing are outside the scope of the present paper and are not included.

II. FORMALISM

The calculation of the transport coefficients in NS cores is based on the transport theory of multi-component Fermi liquids [3 22 23]. We consider here the thermal conductivity coefficient $\kappa_c$, shear viscosity coefficient $\eta_c$, and momentum relaxation rate $J_{ci}$, where indices $c$ and $i$ numerate particle species. It is customary to express these transport coefficients through the effective mean free paths of the quasiparticles as

$$\kappa_c = \frac{\pi^2}{3} T \frac{n_c}{P_{Fc}} \lambda_c^\kappa, \quad (1)$$

$$\eta_c = \frac{1}{5} n_c P_{Fc} \lambda_c^\eta, \quad (2)$$

$$J_{ci} = n_c P_{Fc} (\lambda_{ci}^D)^{-1}, \quad (3)$$

where $T$ is a temperature, $n_c$ is a number density of the particle species $c$, $P_{Fc} = (3\pi^2 n_c)^{1/3}$ is the corresponding Fermi momentum. In Equations (1) and (2), the quantities $\lambda_c^\kappa$ and $\lambda_c^\eta$ are effective mean free paths of the particle species $c$ for the thermal conductivity and shear viscosity problems, respectively, while $\lambda_{ci}^D$ introduced in Equation (3) is an effective mean free path for the momentum relaxation in the collisions between particle species $c$ and $i$. Momentum relaxation rates (3) describe friction between the mixture components. They are related to the traditional diffusion coefficients as $D_{ci} = n_c \mu_c (\partial \log \mu_c / \partial \log n_c)_{T,Fc}^{-1}$. The effective mean free paths in Equations (1)–(3), in general, are not the same and need to be determined from microscopic calculations for the corresponding transport problem. Frequently, one expresses the transport coefficients through the effective relaxation times $\tau_c$ instead of $\lambda_c$ [2]. The relation between these quantities is simply $\lambda_c = v_{Fc} \tau_c$, where $v_{Fc}$ is the Fermi velocity of the particle species $c$.

In order to find effective mean free paths in the degenerate matter of NS cores it is enough to employ the simplest variational solution of the transport equation, which reduces to a solution of a system of linear equations, see Ref. [2] for details. This system reads

$$1 = \sum_i (n_i \sigma_{ci} \lambda_c + n_i \sigma^*_{ci} \lambda_i), \quad (4)$$

where the summation is carried over all components with which the given species $c$ collide, including $i = c, \sigma_{ci}$ and $\sigma^*_{ci}$ are the transport cross-sections for these collisions to be defined below, and we omitted for a moment the upper indices at $\lambda$’s for brevity. The primed cross-sections $\sigma^*_{ci}$ describe the mutual influence of the non-equilibrium distributions of the different particle species. It is instructive to introduce a partial mean free path for the $c$–$i$ collisions $\lambda_{ci} = (n_c \sigma_{ci} + \delta_{ci} n_i \sigma^*_{ci})^{-1}$,

$$\lambda_{ci}' = (n_i \sigma^*_{ci})^{-1}. \quad (5)$$

In principle, all possible pair collisions in the mixture should be included in Equation (4). However, it turns out (e.g., [2 3]) that in the npe NS cores, the system of equations (4) decouples in two subsystems, one of which corresponds to the nuclear sector and other to the electromagnetic one. These sectors can be considered separately. Moreover, only the neutrons as most abundant particles, dominate the nuclear contribution to the transport coefficients. We will discuss this statement in more details in Section IV B. In the present study we focus on the nucleon sector. We closely follow Refs. [6 7] and omit the details.

In order to find the transport cross-sections that appear in Equation (4), one needs to multiply the quasiparticle collision probabilities with certain angular factors depending on the transport problem in question and average the results over the allowed phasespace, see, e.g., Ref. [6]. The collision probability depends on the incoming pair particle state $|ci\rangle$, and the final state of the particles after the collisions $|c'i'\rangle$. Since the particles are degenerate, only the excitations close to the Fermi surface contribute to the transport. Therefore, the magnitudes of all four particle momenta participating in the collision $(p_c, p_i, p_{c'}, p_{i'})$ are fixed to the respective Fermi momenta. Taking into account the conservation of the total momentum $P \equiv p_c + p_i = p_{c'} + p_{i'}$, only two angular variables determine the relative position of the scattering quasiparticle momenta in space. For the nuclear scattering, it is convenient to use the absolute value of the total momentum, $P$, and the value of the transferred momentum, $q$, where $q = p_{c'} - p_c = p_{i'} - p_i$. The latter is connected to the center of mass (c.m.) scattering angle $\theta_{c.m.}$ as

$$\cos \theta_{c.m.} = 1 - \frac{q^2}{2P^2}. \quad (7)$$
where $p$ is the absolute value of the colliding pair relative momentum $p \equiv (p_f - p_i)/2$. Since all quasi-particles are placed on the Fermi surface, the relation $4p^2 + P^2 = 2(p_{Fc} + p_{Fi})$ holds. Notice, that sometimes the other set of variables (e.g., the traditional Abikosov-Khalatnikov angles $\gamma$) can be more convenient depending on the investigated problem. For instance, for the electromagnetic collisions it is more convenient to use the angle between $(p,p_c)$ and $(p,p_c')$ planes instead of $P$ (see, e.g., Ref. [17]).

Let $\langle c'G|c\rangle$ be the scattering transition matrix element, where $G$ is the scattering operator. We define

$$Q_{ci}(P, q) = \frac{1}{4(1 + \delta_{ci})} \sum_{\text{spins}} |\langle c'G|c\rangle|^2,$$

(8)

where the summation is carried over the initial and final spin states. The factor $(1 + \delta_{ci})^{-1}$ is included to avoid double counting of the same collision events in the final expression.\(^1\) We also introduce the phase-space angular brackets for an arbitrary quantity $A(P, q)$ as

$$\langle A(P, q) \rangle = \int_{|pp_c+pp_i|} dq m(q) \int_0 dq_m q_m A(P, q) \sqrt{q_m^2 - q^2},$$

(9)

where $q_m(P)$ is the maximal possible transferred momentum for a given value of $P$. It can be expressed as\([24]\)

$$q_m^2(P) = \frac{4p_{Fc}^2 q_{Fc}^2 - (p_{Fc}^2 + p_{Fi}^2 - P^2)^2}{p^2}.$$  

(10)

Using the definitions\([8]-[9]\), the transport cross-sections for the thermal conductivity problem can be written as\([9]\)

$$\sigma_{ci}^n = \frac{3m_{ci}^* m_{ci}^* T^2}{10 p_{Fc}^2 p_{Fi}^2} \langle Q_{ci} (4p_{Fc}^2 + q^2) \rangle,$$

(11)

$$\sigma_{ci}^{n'} = \frac{3m_{ci}^* m_{ci}^* T^2}{10 p_{Fc}^2 p_{Fi}^2} \langle Q_{ci} (2p_{Fc}^2 + 2p_{Fi}^2 - 2P^2 - q^2) \rangle,$$

(12)

where $m_{ci}^*$ are the particle effective masses at the Fermi surface, so that $v_{Fc} = p_{Fc}/m_{ci}^*$. Similar expressions for the shear viscosity problem, albeit different angular factors, read

$$\sigma_{ci}^n = \frac{3m_{ci}^* m_{ci}^* T^2}{8p_{Fc}^2 p_{Fi}^2} \langle Q_{ci} q^2 (4p_{Fc}^2 - q^2) \rangle,$$

(13)

$$\sigma_{ci}^{n'} = \frac{3m_{ci}^* m_{ci}^* T^2}{8p_{Fc}^2 p_{Fi}^2} \langle Q_{ci} q^2 (2p_{Fc}^2 + 2p_{Fi}^2 - 2P^2 - q^2) \rangle.$$  

(14)

The effective mean free path for the momentum relaxation rate\([3]\) can also be expressed via the corresponding transport cross-section

$$\left(\lambda_{ci}^{Dn_1} \right)^{-1} = \sigma_{ci}^n = \frac{m_{ci}^* m_{ci}^* T^2}{2p_{Fc}^2 p_{Fi}^2} \langle Q_{ci} q^2 \rangle.$$  

(15)

Notice that Equations\([9]\) and\([15]\) imply that the momentum relaxation rates are symmetric, $J_{ci} = J_{ci}$. If the forward scattering, $q \to 0$, dominates, the standard result of the Fermi-liquid transport theory $\sigma_{ci}^n = 3\sigma_{ci}^D$ holds. In the traditional Fermi-liquids, the squared transport amplitude\([8]\) does not depend on the energy transferred in the collisions. In this case the transport cross-sections in Equations\([11]-[15]\) obey the standard $\propto T^2$ temperature dependence. As a consequence, the effective mean free paths are inversely proportional to the temperature squared. This is the case for the nucleon collisions which are the main focus of the present study. For the long-range electromagnetic collisions in relativistic matter, this is no longer the case (see, e.g., Ref.\([2]\) for the review).

Thus, to calculate the nucleon transport cross-sections one needs the squared matrix elements $Q_{ci}$ and the effective masses $m_{ci}^*$ which should be provided by the nuclear many-body theory. Nuclear potentials and hence the scattering amplitudes are conveniently given in a partial wave basis for the interacting pair states in the c.m. frame, $|P, P; J\ell SM\rangle$, where $S$ is the pair total spin, $\ell$ is the pair orbital momentum, $J$ is its total angular momentum, and $M$ is the total angular momentum projection. Then the quantity $Q_{ci}$ can be expanded in the series in Legendre polynomials $P_L (\cos \theta_{cm})$:

$$Q_{ci}(q, P) = \frac{1}{1 + \delta_{ci}} \sum_L Q_{ci}^{(L)}(P) P_L (\cos \theta_{cm}),$$

(16)

where the coefficients of expansion are related to the matrix elements of the transition amplitude in the partial wave basis as\([6]\)

$$Q_{ci}^{(L)}(P) = \frac{1}{16\pi^2} \sum \lambda^{t\ell\ell} L S J \{J L \ell S \ell J\} \left(1 + \delta_{ci}(-1)^{S+\ell}\right) \left(1 + \delta_{ci}(-1)^{S+\ell}\right) G_{ij}^{LS}(P, p, p) \left(G_{ij}^{LS}(P, p, p)\right)^{*}.$$  

(17)

\(^1\) Notice, that this differs from the definition in Refs.\([6, 24]\), where this factor is included at the later stage.
Here $C^{L0}_{0\alpha\beta}$ is the Clebsch-Gordan coefficient, terms in curly brackets are 6j-symbols of the quantum angular momentum theory [25], $\Pi_{ab} \equiv \sqrt{(2a+1)(2b+1)}$, $G^{1S}_{ll}(P, p, p\pi)$ is the matrix element of the operator $\hat{G}$. In Equation (17), the total angular momentum $J$, total nucleon pair spin $S$, and total momentum $P$ are conserved, and summation is carried over all angular momenta and spin variables, except $L$. The collision type index, nm, np, or pp, of the $G$-matrix is omitted for brevity. Terms in brackets containing $\delta_{\ell\ell}$ account for the contribution of exchange terms in case when the collisions between the same species are considered. Using the expansion (16), the integration over $\delta_{\ell\ell}$ in Equation (21), while $\gamma$ is the angle between $k_a$ and $k_b$. The summation over $\alpha$ here includes $\alpha = nn$, np, pn, and pp. We do not show explicitly the isospin index $T$ in Equation (21). It is fixed by the condition $\ell + S$ being odd. For the nn and pp scattering only $T = 1$ channels contribute to the sum in Equation (21), while $T = 0, 1$ contribute to the np $G$-matrix.

We solved the Bethe-Goldstone equation in the partial-wave basis up to total momentum $J = 12$ on a grid of the total baryon number densities spanning from $n_B = 0.05$ to 0.6 fm$^{-3}$ and proton fractions from $x_p = 0$ to 0.5.

Here we analyze the same nucleon-nucleon (NN) interaction potentials as in our previous studies [17, 18]. Namely, we use two realistic two-body potentials: the Argonne v18 (Av18 for short) potential [27] and the charge-dependent Bonn (CD-Bonn for short) potential [28]. It is well-known that the non-relativistic two-body interactions fail to reproduce the saturation point of the symmetric nuclear matter. To this end it is necessary to introduce three-body nuclear forces (tbf). Here, as in the Ref. [18], we include three-body forces in as an effective two-body interaction. This effective two-body interaction is obtained from the three-body one by averaging over the third particle, see Refs. [29, 30] for details.

We investigate two models for the tbf. The first one is the phenomenological Urbana IX (UIX for short) model [31]. This model contains adjustable parameters that were tuned to approach the correct saturation point with the Av18 or CD-Bonn two-body potentials. The second tbf model in our study is the microscopic three-body force (TBFmic for short) model based on the meson-nucleon theory of the nucleon interaction [32, 33]. The TBFmic model investigated here is based on the same meson-nucleon coupling parameters as the Av18 potential, so we use only it in combination with this two-body potential, see Ref. [18] for more details. In total, we show below the results for five different NN interactions: Av18, CD-Bonn, Av18+UIX, CD-Bonn+UIX, and Av18+TBFmic.

The $G$-matrices calculated from the solution of Equation (15) are taken on-shell and on the Fermi surface (so that the starting energy omitted in Equation (17) is $z = e_{c,i}(p_{F_a}) + e_{c,i}(p_{F_b})$) and are substituted into Equations (16) and (17). The effective masses in the Brueckner-Hartree-Fock approach for the potentials studied here were obtained in Ref. [18] that provided the convenient analytical approximations for these quantities. Having $Q_{aa}$ and $m_{c,i}^*$ in hand, we can calculate the effective mean free paths and transport coefficients of nucleons in NS cores.
Figure 1. Effective inverse mean free paths for the thermal conductivity problem as functions of density for the proton fraction $x_p = 0.15$. The coefficients that couple to $\lambda_0^p$ in Equation (4) are shown in the panel (a), while coefficients which couple to $\lambda_0^e$ in Equation (4) are shown in the right panel. Different symbols correspond to different nuclear potentials as detailed in the legend in the left panel. Solid, dashed, and dotted lines show partial contributions from the collisions between the species of same kind, different kinds, and the primed terms, respectively. With the dash-dotted lines in the panel (b) we show the effective inverse mean free paths for the electromagnetic collisions of protons (with e, $\mu$, and p) for three values of temperature, as indicated in the plot. The temperatures are (from the dash-dotted line top to the bottom one) $T = 10^7$, $10^8$, and $10^9$ K.

IV. RESULTS AND DISCUSSION

A. Effective mean free paths

In Figure 1 we plot the partial inverse effective mean free paths (Equation 3) for the thermal conductivity problem for neutrons (Figure 1a) and protons (Figure 1b) as a function of density $n_B$ for a fixed value of the proton fraction $x_p = 0.15$. As detailed in Section 3, the partial mean free paths mediated by NN interactions scale as $T^{-2}$, so we plot combinations $(\lambda^\kappa)^{-1} n_B^{-2}$, where $T_8 \equiv T/(10^8$ K) Solid, dashed, and dotted lines correspond to $\lambda_{nn}^\kappa$, $\lambda_{np}^\kappa$, and $\lambda_{pn}^\kappa$ in the left panel, respectively, and to $\lambda_{pp}^\kappa$, $\lambda_{pn}^\kappa$, and $\lambda_{np}^\kappa$ in the right panel. Notice that we plot $|\lambda_{pn}^\kappa|$ in the left, neutron, panel, while in the right, proton, panel we show $|\lambda_{np}^\kappa|$. This is because these primed quantities couple with the neutron or proton effective mean free paths, respectively, in the system of equations (4). Different symbols correspond to different potentials considered in this paper, as indicated in the legends. The prominent discontinuities in $(\lambda_{pn}^\kappa)^{-1}$ and $(\lambda_{np}^\kappa)^{-1}$ at $n_B \sim 0.45$ fm$^{-3}$ for the Av18+TBFinic interaction (dotted lines with open triangles) are manifestations of the change of sign of these quantities around this density. Notice, that these non-diagonal elements of the scattering matrix in Equation (4) can have any sign. In the conditions of Figure 1, these coefficients are negative except for Av18+TBFinic case at $n_B \gtrsim 0.45$ fm$^{-3}$. In Figure 1b, we also plot with dash-dotted lines the partial inverse mean free path for protons $(\lambda_{p,em}^\kappa)^{-1}$ due to the electromagnetic interaction with all charged particles, leptons (electrons and muons) and also the protons themselves. The mean free paths mediated by electromagnetic interactions are calculated following Ref. [14, 15] and obey non-Fermi liquid temperature dependence due to dynamical character of the plasma screening in the relativistic degenerate plasma [2, 31, 32]. Therefore, $(\lambda_{p,em}^\kappa)^{-1}$ is given for three temperatures, $T = 10^7$, $10^8$, and $10^9$ K. In the leading order, $\lambda_{p,em}^\kappa \propto T^{-1}$ instead of the standard Fermi-liquid dependence. Notice, that $\lambda_{p,em}^\kappa$ depends on the proton effective mass and hence on the NN interaction. In order to not overcrowd the plot even more, in Figure 1b $(\lambda_{p,em}^\kappa)^{-1}$ is shown for the Av18+UX NN interaction only.

The total effective mean free path is limited by the most frequent collisions. In Figure 1a, this corresponds to largest partial inverse mean free paths. Despite differences between the potentials used, one can conclude
that at lower densities, \( n_B \lesssim 0.3 \text{ fm}^{-3} \), the neutron-proton scattering (dashed lines in Figure 1a) dominates the neutron mean free path for the thermal conductivity problem. The reason for this originates in a larger np cross-section due to inclusion of the \( T = 0 \) isospin channel and smaller characteristic c.m. energy for the np scattering in comparison to the nn one [3, 6, 24].

The similar situation is observed for protons (Figure 1b), where the np contribution is always larger than the pp one among the strong interaction scattering channels. The strong interaction part of the proton-proton scattering contributes less to the total proton friction in comparison to how the neutron-neutron scattering contributes to the neutron mean free path because of the small proton fraction. In the case of protons, however, the electromagnetic interaction can play an important role, especially at low temperatures, see Figure 1b.

The dependence on the choice of the NN potential in Figure 1 is clearly seen [7]. At low densities, \( n_B \lesssim 0.2 \text{ fm}^{-3} \), inverse mean free paths calculated for different NN interactions are close, however at higher \( n_B \), the results can diverge by an order of magnitude. The most prominent difference results from the selection of three-body forces.

We plot similar inverse effective mean free paths for shear viscosity in Figure 2. The design of this figure is the same as in Figure 1. As for the case of thermal conductivity, prominent divergence of the curves representing the results for different potentials can be observed at high \( n_B \). In general, the behavior of \((\lambda^\eta)^{-1}\) is similar to \((\lambda^\kappa)^{-1}\). The qualitative difference is in the electromagnetic sector. Comparing Figures 2 and 1, one can notice, that for the shear viscosity problem electromagnetic part of the proton interaction (dashed-dotted lines) does not contribute to the total mean free path for the protons, while for the thermal conductivity, this interaction channel can be dominant. Notice that \(\lambda_p^{\eta,\text{em}}\) scales as \(T^{-5/3}\) (cf. \(\lambda_p^{\kappa,\text{em}} \propto T^{-1}\)) [2].
In the momentum relaxation problem, only the collisions between unlike particle species contribute to the respective relaxation process. In Figure 3, we plot the effective inverse mean free path \( (\lambda_{np})^{-1} \) for neutron-proton collisions which sets the momentum relaxation rate and the ambipolar diffusion timescale in the NS cores [21, 36].

In Figures 4–6 we show the effective inverse mean free paths as functions of \( x_p \) for a baryon density \( n_B = 0.35 \text{ fm}^{-3} \). Actually these values at large \( x_p \gtrsim 0.3 \) are not relevant in practice, since the matter inside the neutron stars is highly asymmetric. Figures 4–6 show that the dependence of the neutron-neutron mean free paths on the proton fraction is modest even at large \( x_p \), while the neutron-proton scattering show considerable \( x_p \) dependence. This is especially clear in Figure 6 which shows \( (\lambda_{np})^{-1} \).
B. Approximation to the exact solution

Having calculated the various partial contributions to inverse mean free paths we are now in position to calculate the transport coefficients in NS cores, i.e. thermal conductivity $\kappa$, shear viscosity $\eta$, and the momentum transfer rate $J_n$. The calculation of the latter is straightforward from the Equation (3). In order to calculate the former two, one needs to solve the linear system of equations (4). For the npe case considered here this is, in general, 4×4 system (or 3×3 system if muons are absent). The electromagnetic and nucleon sectors are coupled via protons which participate both in strong and electromagnetic interactions 3. However, it turns out, that in practice the protons have a little effect on the equation for $\lambda_n$. In contrast, especially at low densities, $|\lambda_{np}^\kappa|^{-1} \lambda_p^\kappa$ is always small, as Figures 1b and 4b show. Thus the protons have a little effect on the equation for $\lambda_n$. Moreover, $|\lambda_{np}^\kappa|^{-1} \lambda_p^\kappa$ is much smaller than the diagonal ones, so they can be ignored. This means that the proton mean free path does not affect the equations for the lepton mean free paths (and vice versa). The proton-proton scattering due to nuclear forces is comparable with the proton-scattering due to electromagnetic forces (see Figures 1b and 4a) at the selected temperature. At larger (smaller) temperatures the nuclear (electromagnetic) interactions will be limiting proton mean free path. In any case, $\lambda_p$ is smaller, and at $T \lesssim 10^8$ K significantly smaller, then one calculated from the inversion of the $\Lambda_N^\kappa$ matrix alone. Moreover, $|\lambda_{np}^\kappa|^{-1} \lambda_p^\kappa$ is always small, as Figures 1b and 4b show. Thus the protons have a little effect on the equation for $\lambda_n$. In contrast, especially at low densities, $|\lambda_{np}^\kappa|^{-1} \lambda_p^\kappa$ can be large, see Figures 1b and 4a, and $\lambda_p^\kappa$ can be strongly affected by the non-diagonal neutron term. Notice, that when important, this term $|\lambda_{np}^\kappa|^{-1} \lambda_p^\kappa$ is found to be negative, which lead to further suppression of $\lambda_p^\kappa$. The solution of the full system (4) with matrices $\Lambda_{np}^\kappa$ and $\Lambda_{em}^\kappa$ is compared in Table I with the simplified solution where protons are taken as passive scatterers. Since proton fraction is small, and their mean free path is also small, protons always give a small contribution. We also show in Table I values of $\kappa_c$ for different particle species and the total thermal conductivity $\kappa$. In the case shown in Table I neglecting proton contribution and selecting the simplified solution lead to error of only 10%.

For the shear viscosity problem, electromagnetic interaction do not affect the proton mean free path at any temperature, see Figures 2b and 3b. Indeed, the matrices $\Lambda_N^\eta$ and $\Lambda_{em}^\eta$ read

$$\Lambda_N^\eta = \begin{pmatrix} n & p \\ 0.74 & -0.03 \\ -0.3 & 1.9 \end{pmatrix} \times 10^6 \text{ cm}^{-1},$$

$$\Lambda_{em}^\eta = \begin{pmatrix} e & \mu & p \\ 2.5 & 0.05 & 0.3 \\ 0.11 & 3.7 & 0.47 \\ 0.15 & 0.12 & 5.45 \end{pmatrix} \times 10^3 \text{ cm}^{-1}.$$
Table I. Mean free paths for different particles for thermal conductivity and shear viscosity problems calculated from the full solution of Equation (4) or the simplified solution (protons act only as scatterers), see text for details. The numbers are calculated for $n_B = 0.35 \text{ fm}^{-3}$, $x_p = 0.15$ and Av18+UX nuclear potential. Thermal conductivity ($\kappa$) and shear viscosity ($\eta$) coefficients are also given.

|          | n   | p   | e   | $\mu$ | tot |
|----------|-----|-----|-----|-------|-----|
| Full solution |     |     |     |       |     |
| $\lambda^e$ (10$^{-6}$ cm) | 0.62 | 0.20 | 0.42 | 0.42 |
| $\kappa$ (10$^{22}$ erg cm$^{-1}$ s$^{-1}$ K$^{-1}$) | 5.32 | 0.53 | 0.83 | 0.58 | 7.26 |
| $\lambda^\eta$ (10$^{-6}$ cm) | 1.33 | 0.69 | 394  | 256  |
| $\eta$ (10$^{19}$ g cm$^{-1}$ s$^{-1}$) | 0.17 | 0.009 | 2.71 | 0.88 | 3.77 |
| Simplified solution |     |     |     |       |     |
| $\lambda^e$ (10$^{-6}$ cm) | 0.60 | –   | 0.42 | 0.42 |
| $\kappa$ (10$^{22}$ erg cm$^{-1}$ s$^{-1}$ g$^{-1}$) | 5.14 | –   | 0.84 | 0.59 | 6.56 |
| $\lambda^\eta$ (10$^{-6}$ cm) | 1.30 | –   | 394  | 256  |
| $\eta$ (10$^{19}$ g cm$^{-1}$ s$^{-1}$) | 0.17 | –   | 2.71 | 0.88 | 3.76 |

Notice a different normalization in Equation (24). Proton mean free path due to nuclear scattering is much smaller than corresponding lepton mean free paths, therefore protons can be treated as passive scatterers only when the lepton shear viscosity is calculated. The difference of temperature scaling for $\lambda^e_\eta$ and $\lambda^\eta_\eta$ is modest, therefore this conclusion holds at any temperatures. According to Equation (24) and Figures 2b and 3, $\lambda^\eta_\eta$ is very small, so that the proton influence on the neutron mean free path calculation is negligible. The solution of the full system of equations in comparison to the simplified solution is also shown in Table I. The relative proton contribution to the shear viscosity is much smaller than the relative proton contribution to the thermal conductivity since $\eta_p$ in Equation (4) is proportional to $x_p^{4/3}$, while $\kappa_p$ in Equation (4) is proportional to $x_p^{2/3}$. Therefore it is always an excellent approximation to neglect the proton contribution to the shear viscosity.

The system of equations (4) corresponds to the simplest variational approximation to the full system of kinetic equations. In principle, for Fermi systems it is possible to construct exact solutions of these transport equations in form of the rapidly converging series [e.g., 3, 22, 23]. The closed expressions are obtained for the Fermi-liquid limit where the transition rates are energy-independent. Since the electromagnetic rates are energy-dependent due to the dynamical character of the plasma screening in the dominant interaction channel, it is not straightforward to obtain the exact solution for the full 4×4 problem. However, the decoupling of the variational solutions discussed above allows on the same grounds to decouple the lepton and neutron sectors in the exact system of transport equations. In the lepton sector it turns out that the variational solution is a very good approximation to the exact solution [14, 15]. For the neutron transport coefficients, the calculations show that the correction to the shear viscosity coefficient do not exceed 5% and can be always neglected [0, 2, 15], while for the thermal conductivity this correction can be accounted for by including a factor $C_n = 1.2$ in Equation (1) valid for all practical situations.

To summarize, in order to calculate thermal conductivity and shear viscosity coefficients from Eqs. (1)–(2) in beta-stable matter of NS cores, one need to solve 2×2 system (1) for $e\mu$ problem, however including the $fp$ scattering channel. For nucleon sector it is enough to consider only neutrons scattering off neutrons and protons. The system of equations (4) then reduces to only one equation for $\lambda_n$ (different for $\kappa$ and $\eta$ problems).

C. Partial wave analysis

The results of the Section [XVIII] showed considerable differences in mean free paths for different nuclear potentials. It is instructive to try to understand this difference by considering different partial wave contributions. Generally speaking, it is not easy to isolate contributions of specific partial waves, since the expression (17) couples the matrix elements from the different partial waves. Still, it turns out that the dominant contribution comes from the isotropic ($L = 0$) part of the scattering probability in Equation (17), with $L > 0$ terms giving less than 20% contribution to the final transport cross-sections. This greatly simplifies an analysis. Indeed, the $L = 0$ term in Equation (17) is

$$Q_{cl}^{(0)} = \frac{1}{16\pi^2} \sum_{JST\ell'q} (2J + 1) (1 + \delta_{ci}(-1)^{S+\ell})^2 |G_{\ell\ell'}^{JS}|^2,$$

being just a weighted sum of squared transition amplitudes for all available transitions between the partial wave states. The integration over $q$ in Equations (17)–(18) is now trivial. Save for the normalization factor, $Q_{ei}^{(0)}$ in Equation (16) is a total scattering cross-section on the Fermi surface (see, e.g., the discussion in Ref. [6]). Thus, in this approximation, transport coefficients are determined by the total cross-section averaged over total momentum $P$ with certain weighting factor (see Appendix B in Ref. [6] for more details). There are several differences in how the $G$-matrix elements enter the expression for scattering versus how they contribute to the binding energy, Equation (21). First of all, in the expression for energy Equation (21), only the diagonal $G$-matrix elements are involved, while the non-diagonal $\ell \neq \ell'$ elements from the coupled partial waves also equally contribute to the final result. Importantly, in Equation (26) all partial wave amplitudes add in squares, so both the repulsive and attractive components increase the total scattering cross-section, while they can compensate each other when combined in the total energy. Finally, the transport scattering occurs at the Fermi surface, while the whole Fermi sea of nucleons contributes to the total binding energy. In particular, this leads to appearance of the effective masses (that represent densities of states on
the Fermi surface [22] in the expressions for the transport cross-sections in Equations (11)–(15).

Figures 1–6 show that when the two-body potential is changed from Av18 to CDBonn one, the difference in mean free path calculations is relatively small. This is reasonable, since both these potentials are from the family of so-called ‘realistic’ potentials designed to reproduce the wealth of the experimental data. On the other hand, different three-body forces lead to considerably different results. Therefore in the rest of this subsection we explore the effects of the three-body forces using only the Av18 potential on the two-body level for brevity. In addition we discuss only nn and np partial mean free paths as practically relevant ones following the arguments in Section IV B.

First, in Figure 7 we show the total binding energy per nucleon, $B/A$, as a function of density for the same proton fraction $x_p = 0.15$. The results are shown for Av18 potential at two-body level and for two three-body interaction models as indicated in the legend. Figures 1–6 show that when the two-body potential is changed from Av18 to CDBonn one, the difference in mean free path calculations is relatively small. This is reasonable, since both these potentials are from the family of so-called ‘realistic’ potentials designed to reproduce the wealth of the experimental data. On the other hand, different three-body forces lead to considerably different results. Therefore in the rest of this subsection we explore the effects of the three-body forces using only the Av18 potential on the two-body level for brevity. In addition we discuss only nn and np partial mean free paths as practically relevant ones following the arguments in Section IV B.

Equations (11), (15) show that the many-body effects enter the expressions for scattering through the squared scattering matrix elements $Q_{ci}$ and through the effective masses $m_{ci}^k$. The neutron-neutron and neutron-proton transport cross-sections contain different effective mass prefactors which can be commonly written as

$$\tilde{M}_{kl} = m_{ni}^{k} m_{ni}^{l}. \quad (27)$$

These are the same factors as introduced for the neutrino emission processes in Ref. [18]. Specifically, the neutron-neutron transport cross-sections contain $\tilde{M}_{40}$ prefactor, similarly to the neutron-neutron bremsstrahlung [18], while the neutron-proton transport cross-sections, like the neutron-proton bremsstrahlung rate, contain the $\tilde{M}_{22}$ prefactor [18]. It is not clear how to isolate the contribution of different partial waves to the nucleon effective masses. Therefore we only consider the overall $\tilde{M}_{kl}$ effect. For the Av18+UIX potential the effective masses are larger than for Av18 or Av18+TBFmic potentials [18] contributing partly to the differences in the results shown in Figures 1–6. In Figure 8 we plot the factor $\tilde{M}_{40}$ appropriate for the neutron-neutron scattering with solid lines. These results show that the effective masses are responsible for about 0.2 dex difference between the Av18+TBFmic and Av18+UIX results and 0.5 dex between Av18 and Av18+UIX results. Similar results are found for the factor $\tilde{M}_{22}$ appropriate for the neutron-proton scattering. These factors are shown for three different NN interactions in Figure 8 with dashed lines. At large densities, effective masses are responsible for a factor of 3 difference between the Av18+UIX results and Av18 results for np scattering, and for a factor of 2 difference between Av18+UIX results and Av18+TBFmic results.

Effective masses are only partially responsible for the differences between the results obtained for different NN
interactions. Another part of the difference comes from the scattering matrix elements. Below we discuss this second contribution for neutron-neutron and neutron-proton scattering, taking the effective mass prefactors $M_{kl}$ out.

Consider first the neutron-neutron scattering. We will show the specific results for the thermal conductivity problem only. The results for the shear viscosity problem are similar. As follows from Equations (16)–(17), the contribution from the isotropic part of the transport cross-section, $Q_{nn}^{(0)}$, to the inverse nn mean free path is

$$
\left( \tilde{\lambda}_{nn}^{\kappa} \right)^{-1} = \left( \lambda_{nn}^{\kappa} \tilde{M}_{tt} \right)^{-1}_{0} = \frac{T^2}{10\pi^2 p_{F}^{2}} \left( Q_{nn}^{(0)} (4p_{F}^{2} - p^{2}) \right),
$$

where $\tilde{M}_{tt}$ factor gets rid of the effective masses and the subscript index 0 indicates that only $L = 0$ contribution is included. Our analysis shows that the dominant contributions to this quantity comes from three partial wave channels, namely $^3P_1$, $^3P_2$, and $^1S_0$. Figure 9 shows the relative contributions of these partial wave channels to $\left( \tilde{\lambda}_{nn}^{\kappa} \right)^{-1}$ as function of $n_B$ for $x_p = 0.15$. For concreteness, the Figure 9 is plotted for the Av18+UIX potential. For other potentials one observes qualitatively similar situation, although the proportion between different channels can vary. Still, these three channels are dominant for any NN potential analyzed in this paper. The dominant channel is the $^3P_1$ one, which relative contribution is shown with the solid line in Figure 9. At very small densities, the $^1S_0$ channel dominates (dash-dotted line in Figure 9), but its contribution at intermediate densities decreases, and the $^3P_2$ channel (dashed line) is more important. The $^1S_0$ channel, which matrix element increases considerably at small $p_i$, is additionally suppressed by the angular weighting factor $4p_{F}^{2} - p^{2} = 4p^{2}$ in Equation (28). At large densities, the $^3P_2$ channel for the UIX tbf becomes important again. At the two-body level, both $^1S_0$ and $^3P_2$ contributions are actually less important at high density. The rest of the contribution to $\left( \tilde{\lambda}_{nn}^{\kappa} \right)^{-1}$ comes from other partial waves as shown with the dotted line in Figure 9. Their individual contributions are small and can not be resolved. In total, they are of the same order of magnitude as the contribution form the higher, $L > 0$, multipole moments in Equations (16)–(17).

In Figure 10 we compare the contributions to $\left( \tilde{\lambda}_{nn}^{\kappa} \right)^{-1}$ from three dominant partial waves in absolute values for the Av18 (filled circles), Av18+UIX (open circles), and Av18+TBFmic (open triangles) NN potentials. In ad-

![Figure 9](image_url)

Figure 9. Relative contributions of different partial wave channels to the $L = 0$ part of the nn scattering inverse mean free path $\left( \tilde{\lambda}_{nn}^{\kappa} \right)^{-1}$ for the thermal conductivity problem defined in Equation (28) as a function of $n_B$ for $x_p = 0.15$. Results for the Av18+UIX potential are shown. Solid, dashed, and dash-dotted lines correspond to the $^3P_1$, $^3P_2$, and $^1S_0$ channels, respectively. Dotted line shows the cumulative contribution from all other channels.

![Figure 10](image_url)

Figure 10. Partial contributions of different partial wave channels to the $L = 0$ part of the nn scattering inverse mean free path $\left( \tilde{\lambda}_{nn}^{\kappa} \right)^{-1}$ for the thermal conductivity problem as a function of $n_B$ for $x_p = 0.15$. Effective mass prefactor is not included, see Equation (28). Solid, dashed, and dash-dotted lines correspond to the $^3P_1$, $^3P_2$, and $^1S_0$ channels, respectively. Dotted line is the total contribution to $L = 0$ part, including the partial waves not shown in the figure. Different symbols correspond to different potentials.
The analysis of the neutron-proton scattering is less transparent. Here we chose the momentum relaxation problem as an example on np scattering, Equation (15). The analysis of the neutron-proton scattering for the thermal conductivity or shear viscosity shows the same

\[
\left(\frac{\lambda_{np}^D}{\rho}\right)_0^{-1} = \frac{T^2}{6\pi^2p_{Fnp}} \left( Q_{np}^{(0)}q^2 \right).
\]

The difference is in the angular factors in Equations (11), (13), and (15) which does not change qualitatively the relative contributions from different partial waves.
rest of the partial waves, and show their total contribution by dotted line in Figure 11. At high densities it is as much as about 30%, however individual contributions are less than 5% thus it is not relevant to discuss them separately. Among them, the next channels in order of importance are $^1P_1$ and $^3D_2$, although this is density- and potential-dependent.

In Figure 12 we plot four main partial wave contributions to $\left(\lambda_T^{np}\right)^{-1}$. One can see that the main contribution, which results in stronger scattering by the Av18+UIX potential in comparison to Av18+TBFmic potential at large $n_B$, comes from the $^3D_2$ partial wave (dashed lines). The scattering of the microscopic three-body force in this channel (dashed line with open triangles) is much smaller than both the Av18+UIX (dashed line with open circles) and bare two-body Av18 result (dashed line with filled circles). For instance, the $^3S_1 - ^3D_1$ contributions for Av18+UIX and Av18+TBFmic is similar. We can conclude that the main difference between the UTX and TBFmic results for np scattering prominent at high densities in Figures 1[6] is partially due to difference in scattering in $^3D_2$ channels and partially due to larger effective masses for the UTX tbf in comparison to the microscopic tbf 15.

D. Practical expressions

According to the results of the previous subsection, the mean free paths in the nucleon sector depend considerably on the selected nuclear potential. Ideally, to perform the consistent study, the transport coefficients should be calculated based on the same microscopic model as the EOS. In practice this is rarely possible. On the other hand, the variations in the results of the microscopic calculations show that it is not possible to obtain the universal expression for the transport coefficients equally applicable for any nucleon EOS of the NS core.

Here we suggest a tradeoff approach between the consistency and universality. That is, we will use mean free paths obtained in the previous sections as a functions of $n_B$ and $x_p$ and use them for any EOS in question. As an example, we employ the BSk21 EOS based on the Brussels-Skyrme nucleon interaction functional 37. Its significant advantage in practice is its fully analytical parameterization. We consider the beta-stable matter in BSk21 NS core. The proton fraction as a function of $n_B$ is of course different than that one obtains for the beta-stable matter with each of the five EOSs based on the microscopic models considered here [13].

We illustrate this approach in the next few Figures. In Figure 13 we show partial contribution of different particle species in npep NS cores to the total thermal conductivity. The temperature-independent (in Fermi-liquid) combination $\kappa_T^0$ is shown. Three panels correspond to three temperatures $T = 10^7$ K (left), $T = 10^7$ K (middle), and $T = 10^9$ K (right). The nucleon mean free paths here are calculated in the Av18+UIX model; taking the different potentials changes the picture quantitatively, but not qualitatively. Solid lines show the partial contributions from neutrons ($n$), protons ($p$), electrons ($e$), and muons ($\mu$), as labelled near the corresponding curves. These values are calculated from the solution of the full 4x4 system of variational equations [4]. The curves marked ‘tot’ in each panel show the total contribution. The dashed lines barely seen in the plots correspond to the simplified approximation discussed in the Section 0. Here $\eta e$ and $n$ sectors are decoupled and protons are treated as passive scatterers. We see that this approximation is very good as expected. The electromagnetic scattering does not obey the Fermi-liquid behavior due to the long range of the interaction, therefore corresponding $\kappa_T T^0$ combinations are not temperature-independent. In the leading order, $\kappa_T$ is independent of $T$ [e.g., 2, 13, 35]. Except for the highest temperatures ($T = 10^9$ K, Figure 13), the neutron contribution is always dominant over the lepton one and the proton contribution can be always neglected.

Similar results for the shear viscosity are plotted in Figure 14. Here the combination $\eta T^2$ is shown which is temperature-independent in Fermi liquids. Again, in the electromagnetic sector the temperature dependence modifies, $\eta e \propto T^{-5/3}$ in the leading order, so the curves $e$ and $\mu$ are different in the three panels of Figure 14. As opposite to the thermal conductivity case (Figure 13), leptons dominate the shear viscosity. Only at the lowest densities and temperatures the neutrons give some contribution (Figure 14a). The decoupled solution is shown with the dashed lines which are unresolved in the figure. Therefore this approximation for shear viscosity is even better than for the thermal conductivity. This is especially so since the leptons dominate and the study of the nucleon shear viscosity is more of the academic interest.

According to previous discussion, among the various partial contributions to mean free paths, in practice one only needs $\lambda_{nn}$ and $\lambda_{np}$. We fitted these quantities by analytical expressions valid in the range $n_B < 0.6$ fm$^{-3}$ and $x_p < 0.5$. The fits have a form

$$\frac{\lambda}{T^3} = \frac{T^3}{10^{-6} \text{ cm}} = x_p n_B \frac{2}{n_0} \sum_{k=0}^{3} \sum_{m=0}^{2} a_{km} \left( \frac{n_B}{n_0} \right)^k x_p^m$$

(30)

where $\zeta = 0$ for $\lambda_{nn}$ and $\lambda_{nn}$, $\zeta = -1/3$ for $\lambda_{np}$, and $\zeta = -1$ for $\lambda_{np}$ and $\lambda_{np}$. The polynomial coefficients $a_{km}$ for five potentials considered in this paper are given in the Table II in Appendix. Expression (30) allows one to calculate the effective partial mean free paths for any EOS. The similar fits for the effective masses are provided in Ref. 15. The total neutron mean free path is calculated from the partial mean free paths as

$$\lambda_n = \frac{1}{\lambda_{nn}^{-1} + \lambda_{np}^{-1}}$$

(31)

The neutron thermal conductivity $\kappa_n$ is then calculated using Equation (1). We also recommend to multiply Equation (1) by a factor $C_\kappa = 1.2$ to correct for the
exact solution. The practical expression for the neutron thermal conductivity reads

$$\kappa_n = 6.8 \times 10^{22} T \left( \frac{n_n}{n_0} \right)^{2/3} \frac{\lambda_n}{10^{-6} \text{ cm}} \text{ erg s}^{-1} \text{ cm}^{-1} \text{ K}^{-1}. \quad (32)$$

Thermal conductivity for the BSk21 EOS calculated according to Equation (32) is shown Figure 15 for all potentials considered in the paper (different symbols, as indicated in the plot legend). As expected, at low densities $n_B \lesssim 0.3 \text{ fm}^{-3}$ the results for various potentials are quite close. However, at larger densities the curves diverge. With dash-dotted lines we show the lepton contribution to the thermal conductivity for three values of temperature as indicated at the curves. As already anticipated, at $T < 10^8 \text{ K}$ the neutron contribution dominates for any microscopic model considered.

The neutron shear viscosity in natural units can be written as

$$\eta_n = 5.7 \times 10^{17} \left( \frac{n_n}{n_0} \right)^{4/3} \frac{\lambda_n}{10^{-6} \text{ cm}} \text{ g s}^{-1} \text{ cm}^{-1}. \quad (33)$$

We show the shear viscosity calculated from Equation (33) in Figure 16. The curves and notations are the same as in Figure 15. The difference between the different potential models is prominent, although somewhat smaller than in the case of thermal conductivity. Despite the large model uncertainty, $\eta_n$ seems to be negligible in comparison to $\eta_{np}$ in all cases of practical interest.

Finally, the similar practical expression for $J_{np}$ (Equation (3)) in natural units reads

$$J_{np} = 2.8 \times 10^{30} \left( \frac{n_n}{n_0} \right)^{4/3} \frac{10^{-6} \text{ cm}}{\lambda_{np}} \text{ g s}^{-1} \text{ cm}^{-3}. \quad (34)$$

In Figure 17 we show the results for the neutron-proton momentum transfer rates. Let us stress that this is an
Figure 15. Thermal conductivity for BSk21 EOS. Lines with symbols show interpolated results for \( \kappa_n \) according to practical expressions for different interaction potentials (as indicated in the legend). Dash-dotted lines show \( \kappa_n \) calculated for three values of temperature, whose logarithms are indicated near the curves.

Figure 16. Shear viscosity for BSk21 EOS. Lines with symbols show interpolated results for \( \eta_n \) according to practical expressions for different interaction potentials (as indicated in the legend). Dash-dotted lines show \( \eta_n \) calculated for three values of temperature, whose logarithms are indicated near the curves.

Figure 17. Neutron-proton momentum transfer rate for BSk21 EOS. Lines with symbols show interpolated results for \( J_{np} \) according to practical expressions for different interaction potentials (as indicated in the legend).

important quantity for the magnetic field evolution modelling, since in high magnetic fields it sets the so-called ambipolar diffusion timescale \( t_{amb} \sim J_{np} R^2 / B^2 \), where \( R \) is the typical scale of the magnetic field. According to Figure 17, at large densities the ambipolar diffusion timescale can vary by an order of magnitude depending on the microscopic model used. We do not compare here \( J_{pn} \) with other (electromagnetic) momentum transfer rates for simplicity. Their expressions which include correct plasma screening can be found elsewhere [16]. More detailed discussion can be also found in Ref. [38].

V. CONCLUSIONS

We have analyzed the dependence of the transport coefficients in nucleon cores of the neutron stars on the selection of the nucleon interaction potential. We employed the non-relativistic Brueckner-Hartree-Fock approach as our microscopic theory. Our results continue the previous studies in Ref. [6] where only the Av18 and Av18+UIX NN interactions were considered. We provide (Section IV D) the practical expressions which allow the transport coefficients calculation for any EOS of the nucleon matter, although these expressions are not fully consistent since one needs to rely on the specific NN interaction, which can be different from the one on which the EOS is based. Our general conclusions are as follows

- The nucleon contribution to transport coefficients, namely thermal conductivity, shear viscosity, and momentum relaxation rate, strongly depends on
the nucleon interaction potential. At small densities, the difference is modest since all models are restricted by the direct and indirect experimental data. At large densities, \( n_n \sim 0.6 \text{ fm}^{-3} \), the difference between the models considered in this paper can reach an order of magnitude.

- The inclusion of the three-body forces in Urbana IX model leads to significant increase in the scattering cross-sections, and, as a result, in decrease in the mean free paths for the quasiparticles and the transport coefficients. The effect of the microscopic three-body force is less prominent.

- The changes in the effective masses on the Fermi surface are equally important compared with the changes in the scattering matrix elements in explanation of the obtained difference between the results of calculations for different potentials. Therefore both effects need to be included in practice.

- The main contribution to the nn scattering comes from the \( \frac{3}{2} P_1 \) partial wave channel, and to lesser extent from the \( \frac{3}{2} P_2 \) and \( \frac{1}{2} S_0 \) channels. The difference in the latter channels between the potentials considered in the paper explains most of the observed difference in final results. In case of the np scattering, many channels equally contribute, however at high densities \( \frac{3}{2} D_2 \) and the coupled \( \frac{3}{2} S_1 - \frac{3}{2} D_1 \) partial wave channels are the most important ones.

- Despite the differences in the microscopic model, the general conclusion is that the neutron (nucleon) contribution to the thermal conductivity \( \kappa \) dominates at \( T \gtrsim 10^8 \text{ K} \), while the lepton contribution to shear viscosity \( \eta \) is always dominant. Notice that this conclusion survives also in the case when the proton pairing is taken into account \[17\].

In our study we did not consider the effects of nucleon superfluidity/superconductivity. It is widely accepted that nucleon and protons in a large part of the NS core can be in the paired states, whose critical transition temperatures are uncertain \[39,41\]. Microscopically, the effects of the nucleon pairing on the calculation of transport coefficients are twofold. First, the quasiparticle spectrum becomes gapped which suppresses the collision probabilities. This effect can be incorporated by inclusion of the certain reduction factors \[15,24\]. Second, the transport equation needs to be written for the Bogoliubov quasiparticles, so that the scattering matrix element which defines the collision integral also modifies (for instance it needs to include the processes related to the nonconservation of such particles), see, e.g., \[12\]. To the best of our knowledge, the modification of the NN scattering matrix elements by pairing has not been considered in NS context. Notice that the hydrodynamics equations in the superfluid/superconducting liquid also change and the multifluid picture needs to be invoked. The systematic study of the effects of nuclear pairing on the transport coefficients deserves a separate study.

**ACKNOWLEDGMENTS**

The authors thank Dr. H.-J. Schulze for providing the subroutine for the TBFmic three-body force calculations. A part of this work was done during the PHAROS COST STSM #MP1304-061014-049724. P.S. Thanks the INFN Sez. di Catania for hospitality. The work was supported by the Foundation for the Advancement of Theoretical Physics and Mathematics “BASIS”, grant 17-13-305-1.

Appendix: Parameters of the mean free path fit

Here we give the coefficients $a_{km}$ in the fitting expression Equation (30) for the effective mean free paths. Table II contains coefficients for calculating $\lambda_{\alpha N}^n$, where $\alpha = \kappa, \eta, D$ and $N = n, p$. In all cases, the mean squared relative error of the fit is less than 5% and the maximal relative fit error does not exceed 15%.
