How photoexcitations evolve into Coulomb-bound electron and hole pairs, called excitons, and unbound charge carriers is a key cross-cutting issue in photovoltaics and optoelectronics. Until now, the initial quantum dynamics following photoexcitation remains elusive in the hybrid perovskite system. Here we reveal excitonic Rydberg states with distinct formation pathways by observing the multiple resonant, internal quantum transitions using ultrafast terahertz quasi-particle transport. Nonequilibrium emergent states evolve with a complex co-existence of excitons, carriers and phonons, where a delayed buildup of excitons under on- and off-resonant pumping conditions allows us to distinguish between the loss of electronic coherence and hot state cooling processes. The nearly \( \sim 1\,\text{ps} \) dephasing time, efficient electron scattering with discrete terahertz phonons and intermediate binding energy of \( \sim 13.5\,\text{meV} \) in perovskites are distinct from conventional photovoltaic semiconductors. In addition to providing implications for coherent energy conversion, these are potentially relevant to the development of light-harvesting and electron-transport devices.
The initial pathways for the photoconversion into exciton populations rely on two dynamic processes mediated by carrier–carrier and –phonon interactions: quantum dynamics leading to conversion of electronic coherence into incoherent populations following polarization dephasing, and cooling of hot states via phonon-assisted energy loss and momentum transfer. In organic photovoltaic systems, the prevailing picture is that photo-generated excitons quasi-instantaneously form during the extremely fast ~10s of fs dephasing times and, then, on a similar time scale, substantially populate interfacial, charge transfer states as e-h polaron pairs.

Because of the limiting long-range charge separation and transfer inherent in such polaron formation, reexamination of the conventional wisdom is being actively pursued in efficient photoconversion systems. Of particular interest are the emerging concepts of quantum coherent transport and hot-conventional wisdom is being actively pursued in efficient photovoltaic systems.

Ultrafast terahertz (THz) spectroscopy provides an unambiguous approach to characterize full response functions of genuine excitons and carriers, as well as their dynamics. Broadband THz pulses probe discrete, internal quantum transitions between bright and dark excitonic Rydberg eigenstates such as 1s → 2p and 1s → 3p, as illustrated in Fig. 1a, which provide a direct measure of excitonic correlations and binding energies. Pump-induced THz conductivity is sensitive to excitons across the entire centre-of-mass momentum K-space. In contrast, the previously-used interband optics only measures a subset of excitons near the bandgap and little absorption is expected. We attribute this to the high background above 820 nm, which is below the perovskite bandgap and little absorption is expected. We attribute this to the high inhomogeneity of perovskite crystals dispersed in PMMA matrix, as confirmed in ref. 29 (See Supplementary Note 4 for details).

We perform optical-pump and THz-probe spectroscopy, which is driven by a 1 kHz Ti:Sapphire regenerative amplifier with 790 nm central wavelength and 40 fs pulse duration. One part of the output is used to pump the sample either directly at the fundamental wavelength of 790 nm or at 399 nm after going through a β-barium-borate (BBO) crystal. The pump spectra are shown in Fig. 1e together with the linear absorption spectra of the CH$_3$NH$_3$PbI$_3$/PMMA film. The other part of the output is used to detect phase-locked THz fields in time-domain via optical rectification and electro-optic sampling of two 0.2 mm thick ZnTe crystals, respectively. This increases by an order of magnitude of the signal-to-noise ratio at the important, high frequency regions in the range of 10–15 meV comparing to 1 mm thick ZnTe emitter/detector. The THz electrical fields exhibit broadband spectral width from 2 to 15 meV used as a probe. To obtain time-resolved complex THz conductivity of the sample, we record the THz electrical fields in time-domain transmitted through a clear aperture $E_{\text{out}}(t)$, static sample $E_{\text{Sample}}(t)$ and its pump-induced change $\Delta E_{\text{Sample}}(t)$ at a fixed pump-probe delay $\Delta t$ (Fig. 2a).

Here we report the direct observation of resonant, internal quantum transitions between excitonic Rydberg states and their distinct formation pathways in a model perovskite CH$_3$NH$_3$PbI$_3$ (or MAPbI$_3$) by measuring the sub-ps resolved, full THz response functions. This precisely yields a binding energy 13.5 meV that appears exclusively below the tetragonal-to-orthohombic structural phase transition at $T_S = 160$ K. Nonequilibrium emergent states evolve with a complex co-existence of excitons, carriers and phonons, where a delayed buildup of excitons under various pumping conditions allows us to distinguish between the loss of electronic coherence and hot state cooling processes. Such initial coherent and cooling dynamics of excitons further elucidate the nearly ~1 ps dephasing time and strong interaction between electron and low-frequency phonons in perovskites that are distinct from conventional semiconductors. In addition to providing implications for coherent energy conversion, these fundamental insights are potentially relevant to the development of light-harvesting and electron-transfer devices.

**Results**

**Experimental scheme and sample characterization.** A 550 μm thick free standing perovskite-poly(methylmethacrylate) (PMMA) thin film was made by embedding μm size CH$_3$NH$_3$PbI$_3$ crystals (Fig. 1b) in the polymer matrix, as shown in SEM image of the CH$_3$NH$_3$PbI$_3$/PMMA film (Fig. 1c). Room temperature X-ray diffraction measurements of the film and pure CH$_3$NH$_3$PbI$_3$ powder corroborate the inclusion of the perovskites into the PMMA matrix (Fig. 1d).

**Correlated THz resonances from excitonic Rydberg states.** Figure 2a allows us to simultaneously obtain the sub-ps,
frequency-dependent complex conductivity $\Delta \sigma_1(\omega)$ (Fig. 2b) and dielectric function $\varepsilon_1(\omega)$ (Fig. 2c), associated with dissipative and inductive responses of the sample (see Methods and Supplementary Note 3). At high temperature above the structural phase transition at $T_S = 160$ K, the 295 K trace exhibits two strong photoinduced bleaching features, that is, negative conductivity ($\Delta \sigma_1 < 0$), at 4.2 and 10 meV. These arise from pump-induced softening of phonon modes in CH$_3$NH$_3$PbI$_3$ at $B_1 \sim 4.2$ meV, $B_2 \sim 8$ meV, and in PMMA at $P_1 \sim 10$ meV (see Supplementary Fig. 4 and Supplementary Note 4). The last two merge into a broad bleaching mode. Below $T_S$, two new bleaching modes become progressively pronounced, as marked in the 8 K trace at $B_1 \sim 3$ meV and $B_2 \sim 6.2$ meV, fully consistent with prior observations. However, remarkable photoinduced absorptive resonances ($\Delta \sigma_1 > 0$), previously unobserved, appear at frequencies above 10 meV, but only below $T_S$. Most intriguingly, the pronounced absorptive resonances, centred at $A_1 \sim 10.1$ meV and $A_2 \sim 12.1$ meV, completely prevail over the bleaching behaviours, as seen in the 8 K trace (Fig. 2b). Figure 2d further shows the resonant absorption significantly increases with decreasing temperature, which cannot be attributed to the phonon bleaching. Moreover, the high energy spectral shapes in $\Delta \sigma_1$ and $\Delta \varepsilon_1$ are characterized by the correlated, dissipative and inductive features of two well-defined $A_1$ and $A_2$ resonances. These point to the internal transitions between Rydberg states, that is, $1s \rightarrow 2p$ and $1s \rightarrow 3p$. We emphasize that the experimental ratio of the oscillator frequencies $A_1/A_2 = 0.835$ is in perfect agreement with the theoretical value $\omega_{1s \rightarrow 2p}/\omega_{1s \rightarrow 3p} = (3/4)/(8/9) = 0.844$ derived from the quantized bound states $E_n = -E_{1s}/n^2$, where $E_{1s} = \mu_e/e^2R_H$, $\mu_e$, $e$, and $R_H$ are the relative effective mass, relative permittivity and Rydberg constant, respectively. This yields excition binding energy $E_{1s} = 13.5$ meV. In addition, the disappearance of the resonances across $T_S$ indicates a sudden drop in $E_{1s}$ below $\sim 2$ meV, our low-frequency resolution, consistent with the tetragonal-to-orthorhombic transition.

To put our observation of resonant quantum transitions of excitonic Rydberg states on a solid footing, we fit the experimentally-determined, sub-ps THz response function by a model that consists of the $1s \rightarrow np$ ($n = 2,3$) excitonic resonances, the ‘local’ resonant phonon bleaching and Drude–Smith responses from disorder-/backscattering-induced transport of unbound carriers (see Methods). The experimentally-determined, sub-ps THz response functions can be fitted by a model that assumes co-existence of excitons, phonons and $e$-$h$ plasma (see Supplementary Note 4):

$$
\tilde{e}(\omega) = \tilde{e}_{1s \rightarrow 2p}(\omega) + \tilde{e}_{1s \rightarrow 3p}(\omega) + \sum_{j,k} e_{phonon}^{j,k}(\omega) + e_{DrudeSmith}(\omega).
$$

(1)

The first two terms describe the $1s \rightarrow np$ ($n = 2,3$) excitonic resonances which are proportional to the effective transition strength $A_{1s \rightarrow np}^X = f_1^{X, np} \Delta \varepsilon_1^{X, np}$, where $f$ is the intra-excitonic oscillator strength, and the plasma frequency $\omega_p^2 = N_X e^2/(\epsilon_0 \mu)$. $N_X$ is the exciton density. This way, $\Delta \varepsilon_1^{X}$ is proportional to the population difference between the two Rydberg states involved in the transitions (Fig. 1a), that is, $\Delta N_{1s \rightarrow np} = N_{1s} - N_{np}$ (ref. 22). Next, the ‘local’ resonant bleaching features are well represented by the third term in equation (1), the sum of the phonon contributions in the CH$_3$NH$_3$PbI$_3$ ($B_{ij} < 1,4$) and PMMA ($P_{jk} \sim 1,2$) (see Supplementary Fig. 4 and Supplementary Note 4). Lastly, the non-resonant component is described by the fourth Drude–Smith term in equation (1), which describes disorder-/backscattering-induced transport of unbound carriers of density $N_{eh}$. The last term is justified from the suppressed $\Delta \varepsilon_1(\omega)$ (Fig. 2b) and rapidly increased $\Delta \varepsilon_2(\omega)$ (Fig. 2c) as $\omega \rightarrow 0$, in contrast to the conventional Drude transport of unbound $e$-$h$ carriers. The Drude-Smith term is proportional to $\omega_p^2 = N_{eh} e^2/(\epsilon_0 \mu)$. Both $\Delta \sigma_1(\omega)$ and $\Delta \varepsilon_1(\omega)$ can be consistently fitted very well over the entire spectral range, up to 14 meV, and temperature ranges (black solid lines in Fig. 2b,c). This is remarkable considering that...
the fit are strongly restrained by the requirement of simultaneously describing both responses over a broad spectral range, and by the distinctly different spectral shapes of the excitons and charge carriers. Therefore, by fitting the experimentally obtained THz response functions with the theoretical model, we are able to calculate the densities of excitons $N_{1s,sp}$ and unbound charge carriers $N_{el}$, as shown in the discussion below.

**Excitonic formation pathways characterized by THz responses.**

To further investigate the buildup of the internal quantum transitions, Fig. 3a highlights the complete characterization of full response functions from three electronic contributions at 8 K after removing the phonon contributions, that is, photo-generated excitons $1s \rightarrow 2p$ (dashed red lines), $1s \rightarrow 3p$ (dashed green lines) and from unbound e-h carriers (dashed blue lines). This has not been possible in prior measurements in the perovskites. Such spectra are plotted in Fig. 3b for various time delays $\Delta t$ under 790 nm excitation at 550 $\mu$J cm$^{-2}$, $T = 8$ K, that is, for pump tuned slightly below the lowest bound, $1s$ exciton (pump #1, Fig. 1e). For such below-resonance pumping we expect to mainly generate electronic coherence at early times with minimum heating since only absorption appears at the high energy tail of the pump spectrum. Remarkably, the $1s \rightarrow 2p$ and $1s \rightarrow 3p$ quantum transitions in $\Delta \sigma_1(\omega)$ exhibit a delayed rise persisting up to $\sim 17$ ps. In strong contrast, excitation of the higher energy, e-h continuum under 399 nm at 120 $\mu$J cm$^{-2}$, $T = 8$ K (pump #2, Fig. 1e) gives rise to much longer buildup times of 10s of ps (Fig. 3c). Such continuum, e-h excitations are unbound and thus expected to lose electronic coherence quasi-instantaneously following the fs pulse, which leads to a hot electron distribution. An excitonic $1s$ population can then be formed only when the continuum of phonons are scattered to cool the hot state. Such a process is slowed down by the requirement of many scattering events and hot-phonon effects.

**Time-dependent densities of excitons and unbound carriers.**

Access to both the 2p and higher-lying, 3p, dark bound states has been very scarce in materials, which allows us to quantitatively analyse distribution functions and cooling curves of excitons in the perovskite system to corroborate these observations. The distinct spectral shapes in Fig. 3b,c allow us to faithfully extract the effective transition strength (see Supplementary Fig. 5 and Supplementary Note 4) and, thereby, densities of excitons (Fig. 4a,b) and unbound carriers (Fig. 4c). For the below-resonance excitation at 790 nm and 550 $\mu$J cm$^{-2}$, Fig. 4a presents the time-evolution of the extracted exciton population differences $\Delta N_{1s,2p} = N_{1s} - N_{2p}$ and $\Delta N_{1s,3p} = N_{1s} - N_{3p}$. They both show the same delayed buildup in time, which yields a nearly time-independent ratio $\Delta N_{1s,2p}/\Delta N_{1s,3p} \sim 98\%$ (red squares in the inset of Fig. 4d). This result indicates that the incoherent exciton population after fs photoexcitation is mostly distributed at the $1s$ state, that is, $\Delta N_{1s,2p} \approx \Delta N_{1s,3p} \approx N_{1s}$. This is, again, in contrast to pump excitation of continuum states at 399 nm and 120 $\mu$J cm$^{-2}$, where the $\Delta N_{1s,2p}$ and $\Delta N_{1s,3p}$ now exhibit substantially longer rise times on 10s of ps time scale and display different temporal dependence (Fig. 4b) as compared to the 790 nm excitation (Fig. 4a). This results in a time-dependent population ratio varying by $> 10\%$ over 60 ps (blue dots in the inset of Fig. 4d). This allows us to extract the cooling curve of the hot state as shown in Fig. 4d, that is, the thermalized, transient electronic temperature $T^*$ as a function of time (see Supplementary Note 4). $T^*$ is $\sim 270$ K after the 399 nm excitation and gradually reaches lattice temperature of 8 K on a 10s of ps time scale (blue dots), while $T^*$ is already close to 8 K after the 790 nm excitation (red squares).
The experimental results. (The detailed THz time scan with 50 fs resolution is shown together in this two-step exciton buildup to (1) the loss of exciton coherence (cyan) is separated for the 8 K trace. The pump fluences are chosen to induce approximately equivalent two-step rise with characteristic times (black line, Fig. 4a) under 790 nm pumping, which displays a fully follows the detailed THz time scan with 50 fs resolution populations associated with the below-resonance pumping difference fluence), respectively. The shaded circles are the effective transition strength 790 nm wavelength and 550 μm cm$^{-2}$ fluence). (b,c) Photoinduced conductivity changes $\Delta \sigma(\omega)$ at several pump-probe delays and $T = 8$ K after excitation at 790 nm (550 μm cm$^{-2}$ fluence) and 399 nm (120 μm cm$^{-2}$ fluence), respectively. The pump fluences are chosen to induce approximately equivalent $\Delta \sigma^{1s-2p}$ for both excitations which allows to underpin their distinctly different rise times.

Figure 3 | Ultrafast THz Snapshots of formation pathways of excitonic Rydberg states. (a) The THz response functions (red dots) measured under 790 nm wavelength and 550 μm cm$^{-2}$ fluence, at $T = 8$ K and pump probe delay $\Delta t = 60$ ps. The fit (black lines), based on the analytical model of equation (1), is the sum of $1s \rightarrow 2p$ (dashed red lines), $1s \rightarrow 3p$ (dashed green lines) and unbound e-h carriers (dashed blue lines). (b,c) Photoinduced conductivity changes $\Delta \sigma(\omega)$ at several pump-probe delays and $T = 8$ K after excitation at 790 nm (550 μm cm$^{-2}$ fluence) and 399 nm (120 μm cm$^{-2}$ fluence), respectively. The shaded circles are the effective transition strength $\Delta \sigma^{1s-2p}$ extracted from photoinduced internal quantum transitions of excitons. The pump fluences are chosen to induce approximately equivalent $\Delta \sigma^{1s-2p}$ for both excitations which allows to underpin their distinctly different rise times.

The distinct rise times of the relatively cold $1s$ exciton populations associated with the below-resonance pumping underpin a formation pathway different from the cooling of high-energy carriers. The time-dependent exciton density faithfully follows the detailed THz time scan with 50 fs resolution (black line, Fig. 4a) under 790 nm pumping, which displays a two-step rise with characteristic times $\tau^{fast} \sim 1.0 \pm 0.03$ ps and $\tau^{slow} \sim 11.2 \pm 1.06$ ps at 8 K (blue dots, Fig. 4e). We attribute this two-step exciton buildup to (1) the loss of exciton coherence and (2) the resonant scattering of $1s$ exciton with finite momentum distribution with discrete THz phonon modes $B_1-B_6$ in CH$_3$NH$_3$PbI$_3$. Initially the formation of incoherent $1s$ exciton populations occurs on a timescale determined by the quantum dephasing time that characterizes the optical coherence-to-population conversion arising from multiple scattering contributions and disorder effects. The linewidths of the observed resonant internal THz transitions indicate optical polarization dephasing times of the order of 1 ps,

Figure 4 | The time-evolution of the exciton distribution distinguishing various processes. (a,b) Exciton population difference $\Delta N_{1s,2p}$ (red diamonds), $\Delta N_{1s,3p}$ (blue dots) as a function of time delay in a logarithmic scale at 8 K for 790 nm (550 μm cm$^{-2}$) and 399 nm (120 μm cm$^{-2}$) excitation, respectively. The detailed THz time scan with 50 fs resolution is shown together in a. The error bars of carrier densities indicate the uncertainty from theoretical fitting of the experimental results. (c) The time-dependent density $N_{1s}$ of unbound carriers for two pumping conditions. (d) Time-dependent ratios of the population difference $\Delta N_{1s,2p}/\Delta N_{1s,3p}$ are shown in the inset, which allows to extract the cooling curves for two pumping conditions. (e) The photoinduced THz transmission under 790 nm and 550 μm cm$^{-2}$ pumping for various temperatures. A two-step rise, $\tau^{fast} \sim 1.0 \pm 0.03$ ps (grey) and $\tau^{slow} \sim 11.2 \pm 1.06$ ps (cyan) is separated for the 8 K trace.
which is consistent with the measured $e_{\text{fast}}$. Subsequently, the presence of discrete phonon states, with energies on the order of 2–8 meV comparable to the exciton kinetic energies, are unique, which make the 1s exciton populations with finite momenta relax to the $K = 0$ state on a timescale of $\tau_{\text{slow}}$. This is much faster than conventional semiconductors. For example, the near-resonant photoexcitation in GaAs relaxes through acoustic phonon scattering which slows thermalization by orders of magnitude because of the absence of THz LO phonons$^2$ (see Discussion and Supplementary Note 5). In addition, the delayed formation is observed becomes faster with increasing temperature, for example, 8 and 100 K versus 160 K in Fig. 4e, consistent with thermally-induced dephasing and phonon scattering.

The density $N_{ch}$ of unbound carriers following 1s photoexcitations is shown in Fig. 4c. The $N_{ch}$ exhibits a quasi-instantaneous, sub-ps generation for both continuum (white squares) and below-resonance (red squares) pumping, that is, the rise times exclusively in the photo-generated excitons (Fig. 4a). The efficient carrier generation is much faster than the exciton formation and independent of pump frequency. Intriguingly, the co-existence of both excitons and localized $e$–$h$ carriers appears to be ‘universal’ in the perovskites even at low temperature where $E_{h} > k_{B}T$. This may be related to below-band-gap trapped states which separate $e$ and $h$ in real space and prevents them from coming close to each other within Bohr radius $\approx 5.2$ nm to bind into excitons. The results of the Drude–Smith fitting, following Fig. 3a (dashed blue lines), yield a DC mobility of $23–69$ cm$^2$V$^{-1}$s$^{-1}$ for our sample.

**Discussion**

Ultrafast intra-Rydberg–state transitions demonstrated here represent one of the most powerful methods to measure exciton formation pathways and high-frequency charge transport at the initial, highly non-equilibrium and non-thermal timescales following light pumping. The complete characterization of full response functions of excitons, charge carriers and phonons have not been possible in prior measurements in the perovskites. On the one hand, the results here show that the non-equilibrium emergent quantum states dynamically evolve with a complex coexistence of excitons, unbound charge carriers and phonons, for example, even at 10s of ps after photoexcitation as demonstrated in Fig. 3a. On the other hand, this allows us to directly reveal, previously inaccessible, multiple sharp quantum transitions and slow buildup of their correlated states under below resonance pumping. Particularly, the sub-ps resolved, transient exciton density in Fig. 4a clearly displays two-step formation pathways, while the unbound charge carriers show no such rise times (Fig. 4c). In addition, the transient temperatures of the excitonic reservoir are directly determined and already close to an initial lattice temperature after ultrafast photoexcitations, as shown in Fig. 4d. These facts unambiguously underpin a formation pathway different from the cooling of hot electronic and phonon reservoirs under the high energy, continuum pumping. Such unprecedented details of the non-equilibrium states are extremely difficult, if not impossible, to obtain from other measurements.

The existence of the distinct initial temporal regime under below-resonance pumping, characterized by a slow formation of the exciton populations, can be consistently explained by the loss of electronic coherence induced by laser light and the incoherent relaxation induced by the scattering of various discrete THz phonons. As it is well-established in prior work of exciton formation in GaAs$^{1,2}$, there are two main processes that contribute to delayed exciton buildup when the pump excites below the exciton peak. First, the laser field couples to coherent $e$–$h$ excitation amplitudes with zero centre-of-mass (CM) momentum when momentum is a good quantum number. In the case of strong disorder or phonon shakeup processes, a distribution of finite CM momentum excitons is excited. As a second step, scattering processes, mainly with phonons, transform such coherent $e$–$h$ pair excitations into incoherent electron and hole populations with different momenta, or redistribute the photoexcited excitons among different CM states along the 1s parabola. Such populations resulting from exciton-phonon scattering grow as the $e$–$h$ polarization dephases following laser excitation. Therefore, initially the buildup of low-energy 1s exciton populations occurs on a timescale determined by the optical polarization dephasing time, which arises from multiple scattering contributions and disorder effects, while later it is dominated by scattering with discrete or continuum phonons. The nearly ps formation time is supported by the linewidths of the observed THz responses, which is also largely consistent with a recent experiment showing $\tau_{2}$ times of the same materials $\sim 600$ fs at 10 K$^{35}$. Second, following dephasing of the laser-driven exciton polarization, higher CM momentum states in the 1s exciton parabola become populated. Subsequently, these exciton populations relax towards the lowest energy states with small momenta by scattering with phonons. Unlike in GaAs and other inorganic semiconductors, here we observe discrete THz phonon states with energies on the order of 2–8 meV, that is, in the few THz range, as shown in Fig. 2b,d. Such phonon energies are comparable to the exciton CM kinetic energies. Excitons with large CM momentum can lose finite kinetic energy by a single scattering event with a discrete phonon, which absorbs the CM momentum. Optical phonons in GaAs are at much higher energy $\sim 36$ meV. Here, the presence of discrete THz phonon states in the perovskite materials can lead to carrier and exciton relaxation on a timescale of few ps, much faster than scattering with acoustic phonons in the case of near–resonance pumping in GaAs $\sim 1$ ns (ref. 2). Comparing between the perovskite materials here and GaAs provides a natural way to explain the similarities and differences in their exciton formation times. This also warrants future investigations to further explore other mechanisms also relevant of explaining these results.

Although our scheme and the samples chosen in this study are mostly relevant for revealing the fundamental ultrafast photo-conversion pathways and electronic coherence, we briefly discuss below about their potential impacts to the perovskite-based devices which operate mostly at room temperatures and in the form of thin films. First, the versatile THz spectroscopy tool shown here allows to measure the full response functions of both excitons and charge carriers under highly non-equilibrium conditions, which has not been possible in prior measurements in perovskite materials. This ultrafast characterization method is extremely relevant for understanding and potentially engineering high-speed electronic and optoelectronic devices. Therefore we expect that such a versatile tool may evolve into a benchmark characterization method for quantitative carrier/exciton management when applied to working devices. Second, the efficient carrier generation revealed here, much faster than the exciton formation even at low temperature, under resonant excitation and in crystal samples, attests the suitability of the perovskite materials for solar cells and photovoltaics. For example, the long exciton formation and cooling times, as compared to GaAs, should benefit the hot-state delocalization scenario for device operation as discussed in ref. 5. In addition, one should expect even more efficient photocarrier generation and quasi-instantaneous probability of energy migration in real device conditions because of the presence of many more defects/grain boundaries and elevated temperatures.

In summary, excitonic Rydberg states with intermediate binding energy, nearly ps dephasing time, and efficient carrier
generation and THz phonon scattering in the perovskites are distinct from conventional semiconductors. The ultrafast, emergent quantum states excited here, being evolving on similar time scales as photocarrier generation and transport, provide clear implications for novel energy migration mechanism involving electronic coherence.

Methods
Sample preparation. Methylammonium iodide (CH$_3$NH$_3$I) and methylammonium lead iodide (CH$_3$NH$_3$PbI$_3$) were prepared by slightly modified literature procedures$^5$. Briefly, hydroiodic acid (10 mL, 0.075 mol) was added to a solution of methylamine (24 mL, 0.192 mol) in ethanol (100 mL) at 0 °C while stirring, and stirring continued for 2 h. The solution was concentrated under vacuum, first in a rotary evaporator at 70 °C, and then under dynamic vacuum at 60 °C for 12 h. The resulting solid was recrystallized from ethanol. A solution of CH$_3$NH$_3$I (9.2 mg, 0.06 mmol) and PbI$_2$ (9.6 mg, 0.02 mmol) in γ-butyrolactone (4 mL) was injected into toluene (15 mL) while stirring, and allowed to stand for 2 h at room temperature. The product was isolated by centrifugation (5 min at 4500 rpm) and washing with toluene (5 mL). We study a free-standing 550 μm thick perovskite-poly(methylmethacrylate) thin film that was made of embedding μm size, CH$_3$NH$_3$PbI$_3$ crystals (Fig. 1b) in PMMA matrix. CH$_3$NH$_3$PbI$_3$ (6 mg, 0.01 mmol) was dispersed in a solution of PMMA (0.13 g, 0.8 μmol) in toluene (3 mL), while sonicating and agitating until the mixture became homogeneous. A homogeneous solution of CH$_3$NH$_3$PbI$_3$ and PMMA in toluene was prepared, cast into a mould and allowed to dry to optical quality films under ambient conditions.

Ultrafast THz conductivity. To obtain the time-resolved, complex THz conductivity of the sample, Fig. 2a shows an example of the measured THz electric fields in time-domain, which are transmitted through a clear aperture (D~50 μm), black) in the absence of pump. It also shows the pump-induced change for a pure PMMA control sample (Fig. 2b) taken as the THz time scan in Fig. 4a (black line) is limited by gate pulse duration. The pump-induced change for a pure PMMA control sample is shown in ref. 32. In the fitting, $\Delta \sigma_{\text{pump}}$ (t) is extracted from the internal, resonant quantum transitions between the Rydberg states $N_0$ and $N_p$ with parameter $c_1$ in the range of ~0.96 to ~1 for all temperatures from 8 to 295 K, which yields a DC mobility of 23–69 cm$^2$/V·s (0.4 THz) for $\varphi$ in our sample. In addition, the observed, broad THz background line shapes can be also fitted by the Drude–Smith model which is identical to the Drude–Smith model in our case for $c_1 = 1$ and $c_2 = 0$ with $p > 1$. The calculated carrier densities from these 2 models are the same, except that the scattering rate of Plasmon model is twice that of Drude–Smith model. Using Plasmon model will not change our conclusion of intra-exciton transitions of the carrier. Given the fact that Plasmon resonances are highly shape dependent, random fluctuations in the sample may make it hard to be applicable.

THz lineshape analysis. For exciton dynamics, our THz lineshape analysis yields the time-evolution of exciton population and carrier density shown in Fig. 4a–c. The resonant coherent excitation regime, the intrinsic microscopic pathway for the buildup of exciton population is shown to originate from the dephasing of electronic coherence and scattering with discrete phonons. The polarization-to-interband excitation conversion time is shown to be on the order of 50 fs instead of THz pulse duration.
excitons generated by the 790 nm pulses are already very cool, close to the lattice temperature at the early stage. Finally, Fig. 4c shows that the photoexcitation quasi-instantaneously convert into mobile carriers, despite the absence of longer range transport hindered by disorder and/or crystal boundary as seen in the suppressed $\Delta E(\omega)$ as $\omega \rightarrow 0$.

Data availability. The datasets generated during and/or analysed during the current study are available from the corresponding author on reasonable request.

Acknowledgements

Work was supported by the US Department of Energy, Office of Basic Energy Science, Division of Materials Sciences and Engineering (scientific driver, spectroscopy experiment, materials synthesis and computational studies), and Division of Chemical Sciences, Geosciences, and Biosciences (materials synthesis). Ames Laboratory is operated for the US Department of Energy by Iowa State University under Contract No. DE-AC02-07CH11358. Terahertz spectroscopy instrument was supported in part by the M. W. Keck Foundation (J.W.).

Author contributions

L.L., Z.L. and J.W. performed the experimental measurements, collected the data and analysed the results. X.Z., Y.Y., K.-M.H. and I.E.P. supported in part by the M. W. Keck Foundation (J.W.).
