(Dated: February 5, 2014)

We study the connections among particle statistics, frustration, and ground-state energy in quantum many-particle systems. In the absence of interaction, the influence of particle statistics on the ground-state energy is trivial: the ground-state energy of noninteracting bosons is lower than that of free fermions because of Bose-Einstein condensation and Pauli exclusion principle. In the presence of hard-core or other interaction, however, the comparison is not trivial. Nevertheless, the ground-state energy of hard-core bosons is proved to be lower than that of spinless fermions, if all the hopping amplitudes are nonnegative. The condition can be understood as the absence of frustration among hoppings. By mapping the many-body Hamiltonian to a tight-binding model on a fictitious lattice, we show that the Fermi statistics of the original particles introduces an effective magnetic flux in the fictitious lattice. The latter can be regarded as a frustration, since it leads to a destructive interference among different paths along which a single particle is propagating. If we introduce hopping frustration, the hopping frustration is expected to compete with “effective frustration”, leading to the possibility that the ground-state energy of hard-core bosons can be higher than that of fermions. We present several examples, in which the ground-state energy of hard-core bosons is proved to be higher than that of fermions due to the hopping frustration. The basic ideas were reported in a recent Letter [W.-X. Nie, H. Katsura, and M. Oshikawa, Phys. Rev. Lett. 111, 100402 (2013)]; more details and several extensions, including one to the spinful case, are discussed in the present paper.

I. INTRODUCTION

In quantum many-body problem, understanding of the ground state is fundamental. The ground-state energy is a physical quantity which governs the stability of the system, and in principle it is measurable by measuring the exchange of the energy with the outside, during a process starting from a known initial state. The ground-state energy also reflects the statistics of identical particles, which pervades all of quantum physics.

In noninteracting systems, the influence of particle statistics on the ground-state energy is quite trivial. The ground-state energy of fermions is simply given by the sum of the lowest single-particle energy eigenvalues, following the Aufbau principle. In contrast, in the ground state of noninteracting bosons, all the bosons condense into the lowest single-particle state, as known as Bose-Einstein Condensation (BEC). Therefore, the ground state energies of bosons and fermions satisfy the “natural” inequality:

\[ E_0^B \leq E_0^F. \] (1)

On the other hand, the comparison of the ground-state energies of bosons and fermions is not trivial in the presence of interaction, because the simple argument based on the perfect BEC breaks down. In a system of interacting bosons, it is in fact already a nontrivial question whether the BEC actually takes place. Einstein’s original argument depends on the absence of interaction. For interacting bosons, there is no general theorem that BEC always occurs\textsuperscript{3,4}. A counterexample is solid \textsuperscript{4}He phase, where BEC is absent even at zero temperature, under a sufficiently high pressure. Rigorously proven examples of BEC (in the sense of the off-diagonal long-range order) in an interacting system are still rather limited\textsuperscript{2,3}.

Even if the occurrence of BEC or the off-diagonal long-range order is proved in a system of interacting bosons, it does not necessarily restrict the ground-state energy, because single-particle states with higher energies can be partially occupied. In strongly correlated systems, the influence of particle statistics on the ground-state energy had not been much explored\textsuperscript{5,6}.

In fact, recently we found\textsuperscript{7} a sufficient condition for the natural inequality (1) to hold, without relying on the occurrence of BEC. That is, if all the hopping amplitudes are nonnegative, the ground-state energy of hard-core bosons is still lower than that of the corresponding fermions. This theorem is extended to the spinful case in the present paper. Once we relax the condition of nonnegative hopping amplitudes, it is possible to reverse the inequality so that the ground-state energy of bosons is higher than that of fermions. We find several concrete models in which such a reversal is realized; and in several cases it is even proved rigorously. More examples and techniques will be introduced in the present paper, than those discussed in Ref. 7. In addition, we also demonstrate the reversed inequality can exist in some interacting systems.

Moreover, our study leads to a novel physical understanding of the effects of particle statistics, in terms of frustration in quantal phase. This is more general than the picture based on the perfect BEC, and is indeed applicable to systems with interaction.

We can map a quantum many-particle problem to a
single-particle problem on a fictitious lattice in higher dimensions. When all the hopping amplitudes are nonnegative and the particles are bosons, the corresponding single-particle problem also has only nonnegative hopping amplitudes. In such a case, there is no frustration in the quantal phase of the wavefunction. On the other hand, Fermi statistics of the original particles gives an effective magnetic flux in the corresponding single-particle problem. This implies a frustration in the phase of the wavefunction, induced by the Fermi statistics. When a magnetic flux is introduced in the original quantum many-particle problem, it also results in a magnetic flux in the corresponding single-particle problem, inducing a frustration. This hopping-induced frustration and the statistical frustration can sometimes partially cancel with each other, resulting in the reversed inequality between the ground-state energies of the hard-core bosons and fermions.

The paper is organized as follows. In Sec. II, we present the full proof of the natural inequality for the spinless case and extend the discussion to the spinful case. Based on the proof, in Sec. III, we put forward a unified understanding of the frustration for bosons and fermions in the same manner. As a by-product, a strict version of the diamagnetic inequality for a general lattice is presented and proved. Several examples, in which the natural inequality is violated owing to the hopping frustration, are presented in Sec. IV. The examples include a simple yet instructive, exactly solvable model of particles on a one-dimensional ring, two-dimensional systems of coupled rings, two-dimensional lattice with magnetic flux, and flat band models. Rigorous proof of the reversed inequality is provided for most cases. Conclusions and discussions are presented in Sec. V.

II. NATURAL INEQUALITY

The natural inequality (1) holds trivially for noninteracting bosons and fermions with the same form of the Hamiltonian. Now we present three theorems, which state that the Eq. (1) holds even for hard-core bosons, provided that all the hopping amplitudes are nonnegative. A brief overview appeared in Ref. 7, but here we give a more detailed discussion, and also an extension to the spinful case.

A. Natural inequality for spinless case

First we consider the comparison of spinless hard-core bosons with spinless fermions. We assume the system of bosons or fermions is described by the same Hamiltonian,

$$\mathcal{H} = -\sum_{j \neq k} (t_{jk} c_j^\dagger c_k + \text{H.c.}) - \sum_j \mu_j n_j + \sum_{j,k} V_{jk} n_j n_k,$$

(2)

where \( j \) is the label of a site on a finite lattice \( \Lambda \) and \( n_j \equiv c_j^\dagger c_j \) is the number of particles on \( j \)-th site. Chemical potential \( \mu \) is the uniform (site independent) part of \( \mu_j \). For a system of bosons, we identify \( c_j \) with the boson annihilation operator \( b_j \) satisfying the standard commutation relations, with the hard-core constraint \( n_j = 0, 1 \) at each site. The hard-core constraint may also be implemented by introducing the infinite on-site interaction \( \frac{U}{2} \sum_j n_j (n_j - 1) \), where \( U \to +\infty \). For a system of fermions, we identify \( c_j \) with the fermion annihilation operator \( f_j \) satisfying the standard anticommutation relations.

This Hamiltonian is very general. We do not make any assumption on the dimension or the geometry of the lattice \( \Lambda \), or on the range of the hoppings. In addition, the interaction is also arbitrary, as long as it can be written in terms of \( V_{jk} \). The interesting aspect of attractive interaction will be discussed at the end of the Sec. II. We note that the Hamiltonian (2) conserves the total particle number. Thus the ground state can be defined for a given number of particles \( M \) (grand canonical ensemble), or for a given chemical potential \( \mu \) (canonical ensemble). The comparison between bosons and fermions can be made in either circumstance.

Now we will present a sufficient condition for the natural inequality (1). Moreover, a sufficient condition for the strict inequality \( E_0^B < E_0^F \) is provided. The proof is also illuminating for physical understanding of the natural inequality in interacting systems.

**Theorem 1.** (Natural inequality for spinless case)

The inequality (1) holds for any given number of particles \( M \) on a finite lattice \( \Lambda \) with \( N \geq M \) sites, if all the hopping amplitudes \( t_{jk} \) are real and nonnegative.

Furthermore, if the lattice \( \Lambda \) is connected, and has a site directly connected to three or more sites, and if the number of particles satisfies \( 2 \leq M \leq N - 2 \), the strict inequality \( E_0^B < E_0^F \) holds.

**Proof.** To write the matrix elements of the Hamiltonian (2), we choose the occupation number basis \( \{ \phi^n \} \equiv \{ \{ n^a \} \} \), where \( M \) is the total number of particles satisfying \( \sum_j n_j^a = M \). The matrix elements of the number operator \( n_j \) are the same for hard-core bosons and spinless fermions in this basis. We begin by defining the operator

$$K_{ab}^B = -K_{ab} F + C \mathbb{1}.$$

(3)

For convenience, we added an identity matrix with large enough diagonal elements \( C \) such that all the eigenvalues \( K_{ab}^B \) of matrix \( K_{ab}^B \) and thus all the diagonal matrix elements \( K_{aa}^B \) are positive. The relation of the matrix elements for bosonic and fermionic operators can be summarized as

$$K_{ab}^B = \begin{cases} |K_{ab}^F| & (a \neq b) \\ K_{aa}^F & (a = b) \end{cases} = |K_{ab}^F|.$$

(4)

The difference between bosons and fermions is that, given nonnegative hopping amplitudes \( t_{jk} \), the matrix elements
of the bosonic operator $\mathcal{K}_\text{B}^\text{B}$ is nonnegative, while those of the fermionic operator $\mathcal{K}_\text{F}^\text{F}$ can be negative. This difference in signs generically leads to different ground-state energies between bosons and fermions.

The ground state of the Hamiltonian $\mathcal{H}_\text{B,F}^\text{B,F}$ corresponds to the eigenvector belonging to the largest eigenvalue $\lambda_\text{max}^\text{B,F}$ of $\mathcal{K}_\text{B,F}^\text{B,F}$. Let $|\Psi_0\rangle_\text{F} = \sum_a \psi_a |\phi^a\rangle_\text{F}$ be the normalized ground state for fermions. The trial state for the bosons can be assumed as $|\Psi_0\rangle_\text{B} = \sum_a |\psi_a| |\phi^a\rangle_\text{B}$, where $|\phi^a\rangle_\text{B}$ is the basis state for bosons corresponding to $|\phi^a\rangle_\text{F}$. Then, by a variational argument,

$$\lambda_{\text{max}}^\text{B} \geq B \langle \Psi_0 | \mathcal{K}_\text{B}^\text{B} | \Psi_0 \rangle_\text{B} = \sum_{ab} |\psi_a| |\psi_b| \lambda_{\text{max}}^\text{B} \geq \sum_{ab} \psi_a^* \psi_b \lambda_{\text{max}}^\text{F} = \lambda_{\text{max}}^\text{F} \tag{5}$$

holds, implying $E_0^\text{B} \leq E_0^\text{F}$. The first part of Theorem 1 is thus proved. As a simple corollary, the ground-state energies for a given chemical potential $\mu$ also satisfy Eq. (1).

In order to prove the strict version of the natural inequality, let us consider $\mathcal{L}^S = (\mathcal{K}^S)^{n}$, where $S = \text{B,F}$, for a positive integer $n$. In the occupation number basis, the matrix element of $\mathcal{L}$ is expanded as

$$\mathcal{L}^S_{ab} = \sum_{c_1,\ldots,c_{n-1}} \mathcal{K}_{ac_1}^S \mathcal{K}_{c_1c_2}^S \mathcal{K}_{c_2c_3}^S \cdots \mathcal{K}_{c_{n-1}b}^S \tag{6}$$

in which each term in the sum represent a particle hopping process among the connected sites.

From the definition of $\mathcal{L}^S$ and the relation between $\mathcal{K}^\text{B}$ and $\mathcal{K}^\text{F}$ denoted by Eq. (4), we have the inequality for matrix elements of $\mathcal{L}^\text{B,F}$:

$$\mathcal{L}^\text{B}_{ab} = \sum_{c_1,\ldots,c_{n-1}} \mathcal{K}_{ac_1}^\text{B} \mathcal{K}_{c_1c_2}^\text{B} \mathcal{K}_{c_2c_3}^\text{B} \cdots \mathcal{K}_{c_{n-1}b}^\text{B} \tag{7}$$

$$\geq \sum_{c_1,\ldots,c_{n-1}} |\mathcal{K}_{ac_1}^\text{F} \mathcal{K}_{c_1c_2}^\text{F} \mathcal{K}_{c_2c_3}^\text{F} \cdots \mathcal{K}_{c_{n-1}b}^\text{F}| = |\mathcal{L}^\text{F}_{ab}|. \tag{8}$$

This applies, in particular, to the diagonal elements with $b = a$.

From Eq. (4), the matrix elements of $\mathcal{K}^\text{F}$ and thus the amplitudes of the process in Eq. (6) can be negative for fermions, while they are nonnegative for bosons. The difference between bosons and fermions shows up exactly when two particles are exchanged. To make two-particle exchange process possible, let us consider a lattice with a “branching” site directly connected to three or more sites. If the number of particle falls in the range $2 \leq M \leq N-2$, two particles can be exchanged from an initial state $|\phi^a\rangle$ and back to the same state in 6 hoppings. An example of particle exchange on a lattice with a branching site is demonstrated schematically in Fig. 1. The contribution to the diagonal elements of bosons $\mathcal{L}^\text{B}_{aa}$ is always positive at $n = 6$, while the contribution to $\mathcal{L}^\text{F}_{aa}$ is negative when two particles are exchanged. On the other hand, there is always a positive contribution to $\mathcal{L}^\text{B}_{\alpha\beta}$ and $\mathcal{L}^\text{F}_{\alpha\beta}$ in the expansion of Eq. (6), at least from the invariant process $c_j = a$ in which no particle moves in $n$ steps. Thus, the strict inequality $\mathcal{L}^\text{B}_{aa} > |\mathcal{L}^\text{F}_{aa}|$ holds in this case.

When the lattice $\Lambda$ is connected, any basis state $|\phi^a\rangle_\text{B}$ can be reached by consecutive applications of the hopping term in $\mathcal{K}^\text{B}$, and thus the matrix $\mathcal{K}^\text{B}_{aa}$ satisfies the connectivity. Together with the property $\mathcal{K}_{ab}^\text{B} \geq 0$, $\mathcal{K}_{ab}^\text{B}$ (and thus also $\mathcal{L}^\text{B}_{ab}$) is a Perron-Frobenius matrix. Applying a corollary of the Perron-Frobenius theorem, we find $\lambda_{\text{max}}^\text{B} > \lambda_{\text{max}}^\text{F}$ and hence the latter part of the theorem follows.

We note in passing that, a consequence of the Perron-Frobenius theorem is that the ground state of bosons has a nonvanishing amplitude $B \langle \phi^a | \Psi_0 \rangle_\text{B}$ with a definite (say, positive) sign for every basis state $|\phi^a\rangle_\text{B}$. This may be understood as a lattice version of the “no-node” theorem.

**B. Natural inequality for spinful case**

Let us now discuss the spinful case. Here we compare spinful hard-core bosons and spinful fermions on a finite lattice, with spin-1/2. This is pseudospin-1/2 for bosons. Namely, we consider the Hamiltonian

$$\mathcal{H} = -\sum_{j \neq k} \sum_{\sigma} \left( t_{jk} c_{j\sigma}^\dagger c_{k\sigma} + \text{H.c.} \right) - \sum_{j\sigma} \mu_j n_{j\sigma}$$

$$+ \sum_{j \neq k} V_{jk} n_{j\sigma} n_{k\sigma'} + \sum_{j} U_j n_{j\uparrow} n_{j\downarrow}, \tag{9}$$

which is a generalization of Eq. (2) with the introduction of the spin degrees of freedom $\sigma = \uparrow, \downarrow$.

Let us first discuss the case in which all $U_j$’s are finite. Then the following simple generalization of Theorem 1 holds:

**Theorem 2.** (Natural inequality for spinful case with finite $U_j$’s)

For any set of finite $U_j$’s, if all the hopping amplitudes $t_{jk}$ are real and nonnegative, the inequality (1) holds for any given number of particles $M \leq 2N$ on a finite lattice $\Lambda$ with $N$ sites. Furthermore, if the lattice $\Lambda$ is connected, and has a site directly connected to three or more site, and if the number of particles satisfies $3 \leq M \leq 2N-3$, the strict inequality holds.
The proof, which is a generalization of Theorem 1, is given as follows.

**Proof.** Since the total number operator $M = \sum_{j\sigma} n_{j\sigma}$ and total magnetization $S_z = 1/2 \sum_j (n_{j\uparrow} - n_{j\downarrow})$ commute with the Hamiltonian (9), one can diagonalize the Hamiltonian in each sub-Hilbert space with fixed values of $M$ and $S_z$. Each sub-Hilbert space has definite numbers of up-spin and down-spin particles. Let $|\phi^\mu\rangle \equiv |\{n_{j\uparrow}^\mu\}\rangle (\mu = 1, 2, \cdots, u)$ be the occupation number basis for up-spin particles, and $|\psi^\nu\rangle \equiv |\{n_{j\downarrow}^\nu\}\rangle (\nu = 1, 2, \cdots, v)$ be the occupation number basis for down-spin particles. Then, we can take the direct product $|\Phi^a\rangle = |\psi^u\rangle \otimes |\phi^v\rangle$, where $a = 1, 2, \cdots, uv$, as the basis of the sub-Hilbert space mentioned above.

The Hamiltonian can be rewritten as:

$$\mathcal{H} = \mathcal{H}_t + \mathcal{H}_{\text{int}},$$

$$\mathcal{H}_t = \mathbb{I}^\uparrow \otimes \mathbb{H}_t^\uparrow + \mathbb{H}_t^\downarrow \otimes \mathbb{I}^\uparrow,$$

where $\mathbb{H}_t^\sigma = -\sum_{j\neq k}(t_{jk}c_{j\sigma}^\dagger c_{k\sigma} + \text{H.c.})$. The matrix elements of the number operator $n_{j\sigma}$ are the same in this basis, for hard-core bosons and fermions. We introduce the operator $\mathcal{K}^{B,F} = -\mathcal{H}^{B,F} + C\mathbb{I}$ with a constant $C$. Choosing $C$ large enough, we make all the eigenvalues and all the diagonal matrix elements of $\mathcal{K}^{B,F}$ positive. The matrix elements of bosonic and fermionic Hamiltonians obey the relation:

$$\mathcal{K}^B_{ab} = \begin{cases} |\mathcal{K}^F_{ab}| & (a \neq b) \\ \mathcal{K}^B_{aa} & (a = b), \end{cases}$$

where the diagonal terms correspond to $\mathcal{H}_{\text{int}}$ and the off-diagonal terms correspond to $\mathcal{H}_t$. With finite $U_j$’s, one site can be occupied by one spin-up particle and one spin-down particle. Thus spin-up particles can move as spinless particles for any given configuration of spin-down particles, and vice versa. Of course, the interaction term $\mathcal{H}_{\text{int}}$, which is diagonal in this basis, is affected by the presence of particles with opposite spins. However, as far as the irreducibility (connectivity) of Hamiltonian is concerned, one can regard the system as two independent systems of hard-core particles. As a consequence, when the lattice $\Lambda$ is connected, any pair of basis states $|\Phi^a\rangle_B$ and $|\Phi^b\rangle_B$ are connected to each other by a successive applications of the hopping term in $\mathcal{K}^B$. Together with the property $\mathcal{K}^B_{ab} \geq 0$, $\mathcal{K}^B$ satisfies the condition of the Perron-Frobenius theorem. When the number of particles $M \geq 3$, there are at least two particles with the same spin. The condition $M \leq 2N - 3$ guarantees there are at least two spaces which can accommodate two particles with the same spin. Thus, when the number of particles falls in the range $3 \leq M \leq 2N - 3$, we can exchange two identical particles and return back to the same state, based on the branch structure as in Fig. 1. Therefore, when $U_j$’s are finite, the lattice is connected and has a branch structure, and $3 \leq M \leq 2N - 3$, two-particle exchange always happens. As in the proof of Theorem 1 for spinless case, the strict inequality $E_0^B < E_0^F$ follows from the Perron-Frobenius theorem.

Now let us discuss the case $U_j = +\infty$. The first half of Theorem 2, the non-strict version of the inequality, remains unaffected by taking $U_j = +\infty$. However, the latter half of Theorem 2, the strict inequality, is affected. The proof of the strict inequality is based on the Perron-Frobenius theorem, which requires the irreducibility of the matrix. For spinless particles and spinful particles with finite $U_j$’s, when the lattice is connected, any pair of occupation number basis states $|\Phi^a\rangle$ and $|\Phi^b\rangle$ of the many-particle problem are connected by consecutive application of particle hoppings. This implies the irreducibility of the matrix representing the many-body Hamiltonian.

However, in the case of spinful system with $U_j = +\infty$, connectivity of the lattice does not guarantee the irreducibility of the many-body Hamiltonian matrix. An illustrative example is the Hubbard model with $U_j = +\infty$ at half filling. Each site is occupied by a particle with either spin up or spin down; there are many basis states corresponding different spin configurations. However, since there is no empty site and double occupancy with spin up and down particles is forbidden, each basis state is not connected by hopping to any other basis state. Therefore, in order to prove the strict inequality, we need some additional condition which guarantees the irreducibility of the Hamiltonian matrix. In fact, the irreducibility of the Hamiltonian matrix at $U_j = +\infty$, and application of the Perron-Frobenius theorem were discussed earlier by Tasaki(12,13) in the context of Nagaoka’s ferromagnetism. Nagaoka’s ferromagnetism is a mechanism of ferromagnetism in the Hubbard model with a single hole with $U_j = +\infty$, and can be understood as a consequence of the Perron-Frobenius theorem. For that, the irreducibility of the Hamiltonian matrix in a certain basis is required. In Ref. 13, a sufficient condition for the irreducibility was presented: if the entire lattice is connected by exchange bonds, then the Hamiltonian matrix in the occupation number basis is irreducible. Here “exchange bond” is defined by a pair of sites which belongs to a loop of length three or four, and the whole lattice remains connected via nonvanishing hopping amplitudes even when the two sites are removed. Thus we obtain

**Theorem 3.** (Natural inequality for spinful case below half filling)

When $U_j$’s are either $+\infty$ or finite, if all the hopping amplitudes $t_{jk}$ are real and nonnegative, the inequality (1) holds for any given number of particles $M \leq N$ on a finite lattice $\Lambda$ with $N$ sites. Furthermore, if the entire lattice $\Lambda$ is connected by exchange bonds, and if the number of particles satisfies $3 \leq M \leq N - 1$, the strict inequality holds.

With infinite on-site repulsion, the maximum number of particles is $N$. The condition $M \geq 3$ is to guarantee there are at least two particles with the same spin such
that they can be exchanged. For a lattice connected by exchange bonds, two particles on an exchange bond can be exchanged without changing the configuration outside, by hopping a hole around the loop on which both the exchange bond and the hole lie.\textsuperscript{13} Hence, when the number of particle }M\text{ satisfies }3 \leq M \leq N - 1\text{, two particles with the same spin can be exchanged on an exchange-bond lattice by successive particle hoppings.

The property that the entire lattice is connected by exchange bonds can be verified\textsuperscript{13} in various common lattices, such as triangular, square, simple cubic, fcc, or bcc lattices, in which nearest neighbor sites are connected by nonvanishing hopping amplitudes. Thus, the above theorem holds for these lattices.

We also note that, Nagaoka’s ferromagnetism only applies to the system with single hole with respect to half filling. However, this restriction is only necessary to guarantee that all the matrix elements are nonnegative. The irreducibility of the Hamiltonian matrix does not require that there is only one hole. In fact, the breakdown of the positivity in the presence of more than one holes in the Hubbard model with }U_j = +\infty\text{ is precisely due to the Fermi statistics of the electrons. If we consider the “Bose-Hubbard model” with spin-1/2 bosons instead of electrons, all the matrix elements are nonnegative in the occupation number basis, for any number of holes. Thus the Bose-Hubbard model with spin-1/2 bosons exhibit ferromagnetism for any filling fraction.\textsuperscript{14} This nonnegativity of the matrix elements for bosons is also essential for Theorem 3, which holds for any filling fraction.

The proofs of Theorems 1 and 2 are insensitive to the signs of the interaction terms }V_{jk}\text{ and }U_j.\text{ Namely the natural inequality holds no matter the interaction is repulsive or attractive. The interesting aspect of the attractive interaction is that it will induce Cooper pair of fermions. In the case of spinless fermions, orbital part of the Cooper pair wavefunction must be antisymmetric with respect to the exchange of two fermions. This results in an extra cost in the kinetic energy. Such a fermionic BEC state thus has a higher ground-state energy than its bosonic counterpart, in full agreement of the Theorem 1.

In contrast, in the case of spinful fermions, with attractive interaction, fermions could pair up in the nodeless }s\text{-channel. In this case, there is no obvious reason why the fermions have a higher ground-state energy than bosons. Nevertheless, according to Theorem 2, spinful fermions still have strictly higher ground-state energy than corresponding bosons, even when the pairing is in the nodeless }s\text{-channel.

This can be interpreted physically in the following way. If the pairing of two particles is completely robust, the problem is reduced to the identical problem of bosonic “molecules”, whether the original particles are fermions or bosons. Then the ground-state energies should be the same for fermions and bosons. However, in general, the pairing is not completely robust, and two pairs can (virtually) exchange each one of their constituent particles. The amplitude for such a process has negative sign only for fermions, leading to the nonvanishing energy difference between fermions and bosons. The exception occurs when the on-site attractive interaction between up and down spin particles is infinite }U_j = -\infty\text{. Then the pairs are completely robust, and no virtual exchange of constituent particles occurs; the ground-state energies for fermions and bosons become identical in this limit. On the other hand, with the infinite attraction, the irreducibility can not be satisfied, because breaking a Cooper pair (or bosonic molecule) costs an infinite energy and is thus prohibited. This implies that the bosonic molecules are completely localized in the model (9). Thus the natural inequality is reduced to the trivial equality }E_0^B = E_0^F\text{ in the limit }U_j \to -\infty\text{.}

![Four-site branch lattice with four spins at half filling and }S_z = 0\text{.}

![Difference of ground-state energy }\Delta E = E_0^B - E_0^F\text{ between hard-core bosons and fermions on the 4-site lattice with a branch, in }S_z = 0\text{ sector with 4 spins. The absolute value of energy difference decreases down to }\sim 10^{-9}t\text{ around }|U|/t = 100\text{.}

In the following, we numerically demonstrate above observations in spinful Bose-Hubbard and Fermi-Hubbard models on a 4-site cluster as shown in Fig. 2. Here the bosons in the “Bose-Hubbard” model still obey a particular hard-core condition }n_{j\sigma} = 0, 1\text{. The Hamiltonian is given by

\[\mathcal{H} = -t \sum_{\langle i,j \rangle} \sum_{\sigma}(c_{i\sigma}^\dagger c_{j\sigma} + \text{H.c.}) + U \sum_j n_{j\uparrow} n_{j\downarrow}, \] (13)

where }t > 0\text{, and }\langle i,j \rangle\text{ denotes a pair of neighboring sites. We consider the spin-1/2 bosons and fermions at half filling (the total number of particles per site }\nu = 1\text{) and }S^z = 0\text{. That is, on this 4-site cluster, there are two up-spin particles and two down-spin particles. The energy difference between spinful bosons and spinful fermions
$(\Delta E = E^B_0 - E^F_0)$ is shown as a function of $U = U_j$ in Fig. 3.

Conforming to Theorem 2, $E^B_0 \leq E^F_0$ holds for all range of $U$, independent of the signs of $U$. Moreover, $\Delta E(U)$ is symmetric along $U = 0$ due to particle-hole symmetry of Hubbard model at half filling $\nu = 1^{15}$.

When $U$ is finite, fermions have strictly higher ground-state energy than bosons, again in agreement with the latter half of Theorem 2. When $U = +\infty$, the present 4-site cluster does not contain any exchange bond, and thus the strict inequality cannot be proven. In fact, in this limit, it is easy to see that the particles are completely immobile and no particle-exchange occurs. The ground-state energy is indeed exactly the same for fermions and immobile and no particle-exchange occurs. The ground-state energy is indeed exactly the same for fermions and bosons in this limit. Likewise, in the limit of $U = -\infty$, either bosons or fermions form completely robust (and immobile) pairs, and the ground-state energies are exactly the same. In the present case, this can also be understood as a consequence of the particle-hole symmetry$^{15}$ at half filling, which maps $U \rightarrow -U$.

III. UNIFIED UNDERSTANDING OF FRUSTRATION AND DIAMAGNETIC INEQUALITY

The role played by frustration is of central importance in the proofs of the theorems. The terminology “frustration” is often used for antiferromagnetically interacting spin system, on geometrically frustrated lattices, such as triangular, kagome and pyrochlore lattices. When there is no global state of the system that minimizes every antiferromagnetic interaction, there is some frustration. More generally, frustration may be applicable to a system with competing interactions, when the ground state does not minimize individual interaction simultaneously$^{16}$.

To see that the sign of hopping amplitudes $t_{jk}$ in a many-body system is related to frustration, it is illuminating to map the hard-core boson problem to a spin-1/2 quantum spin system$^{17}$. The mapping is based on the equivalence between hard-core boson operators and spin-1/2 operators:

$$S^+_j \sim b^+_j, \quad S^-_j \sim b_j, \quad S^z_j \sim b^+_j b_j - \frac{1}{2}. \quad (14)$$

It is then easy to see that a hopping term for hard-core bosons maps to an in-plane exchange interaction:

$$-t_{jk} \left( b^+_j b_k + b^+_k b_j \right) \sim J^+_j \left( S^+_j S^-_k + S^-_j S^+_k \right), \quad (15)$$

where $J^+_j = -2t_{jk}$. Thus the nonnegative $t_{jk}$ corresponds to ferromagnetic interaction, in terms of the spin system. When all the exchange couplings are ferromagnetic, there is no frustration. Namely, every in-plane exchange interaction energy can be minimized simultaneously by aligning all the spins to the same direction in the $xy$-plane. Going back to the original problem of quantum particles, the direction of the spins in the $xy$-plane corresponds to the quantal phase of particles at each site. If all the hopping amplitudes are nonnegative, every hopping term can be simultaneously minimized by choosing a uniform phase throughout the system. In this sense, bosons with nonnegative hopping amplitudes are unfrustrated with respect to their quantal phase.

Let us now consider the case of fermions. Since Fermi statistics brings in negative signs even if all the hopping $t_{jk}$ are nonnegative, it would be natural to expect that Fermi statistics leads to some kind of frustration. However, it is difficult to formulate this based on the above mapping to an $S = 1/2$ spin system. To understand the frustration induced by Fermi statistics in many-particle systems, we introduce an alternative mapping of the many-body Hamiltonian into a single-particle tight-binding model. That is, we identify each of the many-body basis states $|\Phi^a\rangle$ with a site on a fictitious lattice. If two basis states $|\Phi^a\rangle$ and $|\Phi^b\rangle$ are connected by Hamiltonian, $\langle\Phi^b|H|\Phi^a\rangle \neq 0$, there is a link connecting sites $a$ and $b$ in the fictitious lattice. If we can start from an initial state, and return back to the same state by successive applications of the Hamiltonian (2), there is a loop in the fictitious lattice. For bosons, there is no extra phase in the loop. In other words, the fictitious lattice for hard-core bosons is flux free. Therefore, there is no frustration for bosons because there is a constructive interference among all the paths. In contrast, for fermions, in the original many-body problem, if two particles are exchanged and the system returns back to the initial state, the system acquires an extra $\pi$ phase. Upon the mapping to the single-particle problem, this is equivalent to the presence of a $\pi$-flux in the corresponding loop in the fictitious lattice. This can be interpreted as frustration, which causes destructive interferences among different paths.

For a single-particle tight-binding model, introduction of a flux always raises or does not change the ground-state energy, which is known as diamagnetic inequality$^{18}$. The first half of Theorem 1, which states the non-strict inequality, may be then regarded as a corollary of the diamagnetic inequality. On the other hand, the latter half of the Theorem 1 concerning the strict inequality does not, to our knowledge, follow from known results on the diamagnetic inequality. In fact, the arguments in the proof of Theorem 1 can be applied to a strict version of the diamagnetic inequality on general lattices. The general result can be summarized as follows.

Theorem 4. (General diamagnetic inequality and its strict version)

Let us consider a single particle on a finite lattice $\Xi$, with the eigen equation

$$-\sum_{\beta \in \Xi} \tau_{\alpha \beta} \psi_\beta = E \psi_\alpha. \quad (16)$$

In general, $\tau_{\alpha \beta}$ is complex, with $\tau_{\alpha \beta} = \tau^*_{\beta \alpha}$. The ground-state energy $E_0$ for a given set of the hopping amplitudes
\( \{ \tau_{\alpha \beta} \} \) satisfies
\[
E_0(\{ \tau_{\alpha \beta} \}) \leq E_0(\{ \tau_{\alpha \beta} \} ) \tag{17}
\]
Furthermore, the strict inequality,
\[
E_0(\{ \tau_{\alpha \beta} \}) < E_0(\{ \tau_{\alpha \beta} \} ) \tag{18}
\]
holds, provided that the lattice \( \Xi \) is connected and there is at least one loop which contains a nonvanishing flux. A sequence of sites \( \{ \alpha_0, \alpha_1, \alpha_2, \ldots, \alpha_n \} \), which satisfies \( \alpha_1 \neq \alpha_{i+1}, \tau_{\alpha_i \alpha_{i+1}} \neq 0 \) and \( \alpha_n = \alpha_0 \) is called a loop. The loop contains a nonvanishing flux when the product
\[
\tau_{\alpha_0 \alpha_1} \tau_{\alpha_1 \alpha_2} \tau_{\alpha_2 \alpha_3} \cdots \tau_{\alpha_{n-1} \alpha_n} \tag{19}
\]
is not positive (either negative or not real).

**Proof.** The proof is similar to that of Theorem 1. We can define the matrices \( \mathcal{K}, \mathcal{K}' \) by
\[
\mathcal{K}_{\alpha \beta} = \tau_{\alpha \beta} + C \delta_{\alpha \beta}, \tag{20}
\]
\[
\mathcal{K}'_{\alpha \beta} = \tau'_{\alpha \beta} + C \delta_{\alpha \beta}, \tag{21}
\]
with a sufficiently large constant \( C \) so that \( \mathcal{K} \) and \( \mathcal{K}' \) is positive definite. We then define \( \mathcal{L} \equiv \mathcal{K}^n \) and \( \mathcal{L}' \equiv \mathcal{K}'^n \), for the length \( n \) of the loop with a nonvanishing flux. The positive definiteness of \( \mathcal{K} \) and \( \mathcal{K}' \) implies that \( \mathcal{L} \) and \( \mathcal{L}' \) are also positive definite, and thus all the diagonal matrix elements \( \mathcal{L}_{\alpha \alpha} \) and \( \mathcal{L}'_{\alpha \alpha} \) are strictly positive. Similarly to the proof of Theorem 1, \( \mathcal{L}'_{\alpha \beta} \geq |\mathcal{L}_{\alpha \beta}| \) holds for any \( \alpha, \beta \).

In particular, the diagonal matrix elements of \( \mathcal{L}' \) and \( \mathcal{L} \) are expanded as
\[
\mathcal{L}'_{\alpha_0 \alpha_0} = \sum_{\alpha_1, \ldots, \alpha_{n-1}} \mathcal{K}'_{\alpha_0 \alpha_1} \mathcal{K}'_{\alpha_1 \alpha_2} \cdots \mathcal{K}'_{\alpha_{n-1} \alpha_0}, \tag{22}
\]
\[
\mathcal{L}_{\alpha_0 \alpha_0} = \sum_{\alpha_1, \ldots, \alpha_{n-1}} \mathcal{K}_{\alpha_0 \alpha_1} \mathcal{K}_{\alpha_1 \alpha_2} \cdots \mathcal{K}_{\alpha_{n-1} \alpha_0}. \tag{23}
\]
Each term in the expansion satisfies
\[
\mathcal{K}'_{\alpha_0 \alpha_1} \mathcal{K}'_{\alpha_1 \alpha_2} \cdots \mathcal{K}'_{\alpha_{n-1} \alpha_0} \geq |\mathcal{K}_{\alpha_0 \alpha_1} \mathcal{K}_{\alpha_1 \alpha_2} \cdots \mathcal{K}_{\alpha_{n-1} \alpha_0}|, \tag{24}
\]
thanks to \( \mathcal{K}'_{\alpha \beta} \geq |\mathcal{K}_{\alpha \beta}| \). By assumption, there is a nonvanishing contribution to \( \mathcal{L}_{\alpha_0 \alpha_0} \) from the loop of length \( n \),
\[
\mathcal{K}_{\alpha_0 \alpha_1} \mathcal{K}_{\alpha_1 \alpha_2} \cdots \mathcal{K}_{\alpha_{n-1} \alpha_0} = \tau_{\alpha_0 \alpha_1} \tau_{\alpha_1 \alpha_2} \cdots \tau_{\alpha_{n-1} \alpha_0}, \tag{25}
\]
which is not positive. Here we used the fact that the off-diagonal elements of \( \mathcal{K} \) and \( \tau \) are identical. Combining with the contribution from its reverse loop
\[
\mathcal{K}_{\alpha_{n-1} \alpha_n} \mathcal{K}_{\alpha_{n-2} \alpha_{n-1}} \cdots \mathcal{K}_{\alpha_0 \alpha_1}, \tag{26}
\]
which is the complex conjugate of Eq. (25), we find the strict inequality
\[
\mathcal{K}'_{\alpha_0 \alpha_1} \mathcal{K}'_{\alpha_1 \alpha_2} \cdots \mathcal{K}'_{\alpha_{n-1} \alpha_0} + c.c. \ 
\geq \mathcal{K}_{\alpha_0 \alpha_1} \mathcal{K}_{\alpha_1 \alpha_2} \cdots \mathcal{K}_{\alpha_{n-1} \alpha_0} + c.c.. \tag{27}
\]
Thus \( \mathcal{L}'_{\alpha_0 \alpha_0} > \mathcal{L}_{\alpha_0 \alpha_0} > 0 \). Invoking the Perron-Frobenius theorem again, the strict diamagnetic inequality (18) is proved. \( \square \)

The non-strict version is the standard diamagnetic inequality. However, the strict inequality obtained here appears new, also in the general context of diamagnetic inequality.

Mapping of the original quantum many-particle problem to the single-particle problem on a fictitious lattice provides a unified understanding of frustration of quantal phase. When there is a nonvanishing flux in the original many-particle problem, we observed that there is a frustration among local quantal phases, which we may call hopping frustration. On the other hand, when the particles in the original problem are fermions, there is also a frustration among quantal phases, which we name statistical frustration. In the original many-particle problem, the statistical frustration appears rather different from the hopping frustration. However, upon mapping to the single-particle problem on the fictitious lattice, both hopping frustration and statistical frustration are represented by a nonvanishing flux in the fictitious lattice. This provides a unified understanding of hopping and statistical frustrations.

A system of many bosons with only nonnegative hopping amplitudes \( t_{jk} \) represents a frustration-free system. Introduction of any frustration into such a system is expected not to decrease the ground-state energy. For example, introduction of magnetic flux (hopping frustration) does not decrease the ground-state energy. This is a lattice version of Simon’s universal diamagnetism in bosonic systems.\(^{19}\)

On the other hand, when one type of frustration already exists, the effect of introducing another type of frustration is a nontrivial problem. For example, in a system of fermions, the statistical frustration exists. What happens if one further introduces hopping frustration (magnetic flux)? In such a case, there cannot be a general statement: the ground-state energy may or may not decrease, depending on the system in the question. That is, diamagnetism is not universal in spinless fermion systems. Correspondingly, the orbital magnetism of fermions can be either paramagnetic or diamagnetic, depending on the model.

This means that, in some cases, the hopping frustration may (partially) cancel the effect of statistical frustration, so that the introduction of the hopping frustration actually decreases the ground-state energy. The possibility of partial cancellation between the two kinds of frustrations can be again naturally understood by the mapping to the single-particle problem on a fictitious lattice. Each of the frustrations introduces a particular pattern of magnetic flux in the fictitious lattice. It is certainly possible that these two magnetic flux (partially) cancel with each other.
IV. VIOLATION OF THE NATURAL INEQUALITY

In the following, we discuss how the natural inequality can be violated. Theorems 1 and 2 leave the possibility of violation of the inequality by introducing a hopping frustration, that is, by choosing negative or complex hopping amplitudes $t_{jk}$. However, the hopping frustration is a necessary but not sufficient condition to reverse the natural inequality. We will demonstrate that the violation of natural inequality indeed happens in several frustrated systems. For simplicity, we limit ourselves to the comparison between spinless fermions and hard-core bosons, with no other interaction than the hard-core constraint. The case with other interactions will be discussed at the end of this section.

A. Particles on a ring

We start with the best understood and solvable model in one dimension:

$$\mathcal{H} = -\sum_{j=1}^{N} (c_{j}^\dagger c_{j+1} + \text{H.c.}).$$  \hfill (28)

The hard-core boson version of this model, which is equivalent to the spin-1/2 XY chain, can be mapped to free fermions on a ring by Jordan-Wigner transformation\textsuperscript{20,21}. Thus energy eigenvalue problem of hard-core bosons and fermions on a ring are almost the same, except for the subtle difference in the boundary condition. For the periodic or antiperiodic boundary conditions $c_{N+1} = \pm c_{1}$, the Jordan-Wigner fermions $\tilde{f}_{j}$ obey the boundary condition $\tilde{f}_{N+1} = \mp e^{i\pi M} \tilde{f}_{1}$, where $M$ is the number of Jordan-Wigner fermions (equals to the number of bosons). If $M$ is assumed as even, it implies that hard-core bosons with the periodic (antiperiodic) boundary condition is mapped to free fermions with the antiperiodic (periodic, respectively) boundary condition.

Now let us discuss the dependence of the ground-state energy on the boundary condition. Assuming $M = N/2$ is even, the ground-state energy density (ground-state energy per site) is given as

$$\epsilon_{0} = \frac{E_{0}}{N} = -\frac{2}{N} \sum_{k} \cos k,$$  \hfill (29)

where $k$ is taken over all the momenta in the Fermi sea, $-\pi/2 \leq k < \pi/2$. For the periodic boundary condition, the wavenumber $k$ is quantized as $k = 2\pi n/N$, while $k = \pi(2n+1)/N$ for the antiperiodic boundary condition, where $n (-N/4 \leq n < N/4)$ is an integer.

The ground-state energy density asymptotically converges, in the thermodynamic limit $N \to \infty$, to the same integral for either boundary condition. Nevertheless, it does depend on the boundary condition for a finite $N$.

The difference of ground-state energy is exactly calculated as

$$\frac{E_{0}^\text{PBC}}{N} - \frac{E_{0}^\text{APBC}}{N} = \frac{2(1 - \cos(\pi/N))}{N \sin(\pi/N)} > 0,$$  \hfill (30)

for any $N > 1$. The antiperiodic boundary condition gives the lower ground-state energy. The leading order of difference can be extracted in the limit of large $N$ as,

$$\frac{E_{0}^\text{PBC}}{N} = -\frac{2}{\pi} + \frac{2\pi}{3N^{2}} + \frac{2\pi^{3}}{45N^{4}} + O\left(\frac{1}{N^{6}}\right),$$  \hfill (31)

$$\frac{E_{0}^\text{APBC}}{N} = -\frac{2}{\pi} - \frac{\pi}{3N^{2}} - \frac{7\pi^{3}}{180N^{4}} + O\left(\frac{1}{N^{6}}\right),$$  \hfill (32)

for the periodic (PBC) and antiperiodic (APBC) boundary conditions. The leading term of $O(1/N^{2})$ is also determined by conformal field theory.\textsuperscript{22,23} It can be seen that the noninteracting fermions on a ring have a lower ground-state energy with the antiperiodic boundary condition.

As a result, with periodic boundary condition, hard-core bosons have a lower ground-state energy than fermions, in full agreement with Theorem 1. On the other hand, the ground-state energy of hard-core bosons is higher than that of fermions with anti-periodic boundary condition. The anti-periodic boundary condition can be understood as a result of insertion of $\pi$-flux inside the ring. This hopping frustration cancels the statistical frustration so that the natural inequality is violated.

This example of tight-binding model may look trivial, and indeed the calculation itself has been known for years. Nevertheless, it is very useful in highlighting the central physics of the problem, that is, the effect of the statistical frustration of fermions can be canceled by the flux or hopping frustration. The present finding can also be applied to construction of more nontrivial examples, as we will discuss in the Sec. IV B.

B. Coupled rings

Since hard-core bosons have a higher ground-state energy than fermions on a ring containing $\pi$ flux inside the ring as proved in Sec. IV A, we can construct a series of systems where $E_{0}^\text{B} > E_{0}^\text{F}$, by taking many such small rings and connecting them with weak hoppings. If the inter-ring hoppings are weak enough, they are expected not to revert the inequality and $E_{0}^\text{B} > E_{0}^\text{F}$ would be kept.\textsuperscript{24}

We prove rigorously that, the reversed natural inequality is indeed still kept in coupled $\pi$-flux rings, connected by weak hoppings, even in the thermodynamic limit. The first example is $\pi$-flux octagon-square model. The lattice structure is shown in Fig. 4 (a), where one unit cell is shown in green with basis vectors $\vec{a}_{1} = (3, 0)$ and $\vec{a}_{2} = (0, 3)$. The hopping amplitudes on thick and broken lines are denoted by $t$ and $t'$, respectively. The Hamilto-
where “thick, oriented” and “broken” refer respectively to the links drawn with arrows and those drawn as broken lines in Fig. 4(a). We also assume $t > t' > 0$.

By the choice of $e^{i\pi/4}$ hopping phase on the oriented thick lines, there is a $\pi$ flux in every square. Therefore, it can be regarded as a model of coupled $\pi$-flux rings by weak hopping $t'$. In order to prove $E_0^B > E_0^F$ rigorously in the coupled rings, we seek a lower bound for $E_0^B$ and an upper bound for $E_0^F$. If the former is higher than the latter, the desired inequality is proved. We introduce the positive semi-definite operators,

$$A = t' \sum_{(i,j) \in \text{Broken}} (c_i^\dagger + c_j^\dagger)(c_i + c_j) \geq 0,$$

$$B = t' \sum_{(i,j) \in \text{Broken}} (c_i^\dagger - c_j^\dagger)(c_i - c_j) \geq 0,$$

where $A \geq 0$ means $\langle \Phi | A | \Phi \rangle \geq 0$ for any state $| \Phi \rangle$. Therefore, the Hamiltonian for fermions and bosons can be written as

$$\mathcal{H}^F = \tilde{\mathcal{H}}^F - A = \sum_\phi h_\phi^F - A,$$

$$\mathcal{H}^B = \tilde{\mathcal{H}}^B + B = \sum_\phi h_\phi^B + B,$$

where $h_\phi^F = -t \sum_{i=1}^4 (e^{i\pi/4} c_i^\dagger c_{i+1} + \text{H.c.}) + t' \sum_{i=1}^4 c_i^\dagger c_i$ and $h_\phi^B = -t \sum_{i=1}^4 (e^{i\pi/4} c_i^\dagger c_{i+1} + \text{H.c.}) - t' \sum_{i=1}^4 c_i^\dagger c_i$, the cluster Hamiltonians defined on a solid-line square for fermions and bosons, respectively. Noticing $h_\phi$ commutes with each other, the ground-state energy of $\tilde{\mathcal{H}}$ is simply given by the summation:

$$\tilde{E}_0 = \sum_{\phi} \epsilon_{\phi},$$

where $\tilde{E}_0$ and $\epsilon_{\phi}$ are the ground-state energy of $\tilde{\mathcal{H}}$ and that of $h_\phi$ on $\phi$-th $\pi$-flux square, respectively.

Because the operators $B$ is positive semi-definite, the ground-state energy of bosons satisfies

$$E_0^B = \langle \Phi | \tilde{\mathcal{H}}^B | \Phi \rangle \geq \langle \Phi | h_\phi^B | \Phi \rangle \geq \tilde{E}_0^B = \sum_{\phi} \epsilon^B_{\phi},$$

where $| \Phi \rangle$ is assumed as the ground state of $\mathcal{H}^B$.

On the other hand, an upper bound of fermions can be derived as,

$$E_0^F = \langle \Psi | \tilde{\mathcal{H}}^F | \Psi \rangle \leq \langle \Psi | h_\phi^F | \Psi \rangle = \tilde{E}_0^F = \sum_{\phi} \epsilon^F_{\phi},$$

where $| \Psi \rangle$ and $| \Psi \rangle$ are the ground states of $\mathcal{H}^F$ and $\tilde{\mathcal{H}}^F$, respectively.

By exact diagonalization, we obtain the ground-state energies $\epsilon_{\phi}^{B,F}(m)$ in given $m$ particles sectors, shown in Table I.

The number of unit cells is assumed as $N$, from the results of exact diagonalization, a lower bound for bosons is given by $E_0^B \geq -2N(t + t')$ when $t'/t \leq 2 - \sqrt{2}$, or $E_0^B \geq -N(\sqrt{2}t + 3t')$ when $2 - \sqrt{2} < t'/t < 1$. An upper bound for fermions is given by the $E_0^F$, which is dependent on the density pattern on the whole lattice. At half filling, an upper bound of fermions is obtained as $E_0^F \leq -2N(\sqrt{2}t - t')$. Thus, when the ratio falls in this range $t'/t \leq (\sqrt{2} - 1)/2$, we have $E_0^B \geq E_0^F$. Instead of searching an upper bound of fermions, the ground-state energy of fermions can be exactly calculated at certain filling. For convenience, $t$ is set equal to 1. In the single particle sector, the exact dispersion relations are obtained by Fourier transformation:

$$E^{(1)}_{\pm} = \pm \sqrt{(t')^2 + 2 - 2t' \sqrt{1 - \sin (3k_x) \sin (3k_y)}},$$

$$E^{(2)}_{\pm} = \pm \sqrt{(t')^2 + 2 + 2t' \sqrt{1 - \sin (3k_x) \sin (3k_y)}},$$

where $(k_x, k_y)$ is the wavenumber which belongs to the reduced Brillouin zone $-\pi/3 \leq k_{x,y} < \pi/3$. The ground-state energy of fermions at $\mu = 0$, which corresponds to the half filling, is given as

$$E_0^F = \sum_{k_x, k_y} [E^{(1)}_{\pm}(k_x, k_y) + E^{(2)}_{\pm}(k_x, k_y)].$$

TABLE I. The ground-state energies of fermions and hard-core bosons on a thick-line square, where $m$ is the number of particles on a $\pi$-flux square.
Under the assumption that the lattice is of size $9L^2$, the number of unit cells $N$ equals $L^2$. In the thermodynamic limit $L \to \infty$, the ground-state energy of fermions per unit cell at half filling is given by the integral of the lowest two bands (shown in Fig. 4 (b)) in the reduced Brillouin zone,

\[ E_0^{F} = - \int_{-\pi}^{\pi} \frac{dk_x}{2\pi} \int_{-\pi}^{\pi} \frac{dk_y}{2\pi} \left[ \sqrt{(t')^2 + 2 + 2t'\sqrt{1 - \sin k_x \sin k_y}} + \sqrt{(t')^2 + 2 - 2t'\sqrt{1 - \sin k_x \sin k_y}} \right]. \]

(42)

It is easily verified that the reversed natural inequality holds with small ratio of $t'/t$, by comparison of the lower bound of bosons and numerical integral of Eq. (42) with given value of $t'$. For example when $t = 1$ and $t' = 0.1$, $E_0^{B} \geq -2.2N > E_0^{F} = -2.831967N$. When $t' = 0.4$, $E_0^{B} \geq -2.8N > E_0^{F} = -2.885971N$. The results obtained by two approaches are consistent with each other.

The second example is the $\pi$-flux hexagon-triangle lattice, which is shown in Fig. 5 (a). One unit cell is shown in green in Fig. 5 (a), with basis vectors $\vec{a}_1 = (0, 1)$ and $\vec{a}_2 = (1/2, \sqrt{3}/2)$. The Hamiltonian is defined as

\[ H = -t \sum_{(i,j) \in \text{thick, oriented}} c_{i}^{\pi/3}c_{j}^{\dagger} - t' \sum_{(i,j) \in \text{broken}} c_{i}^{\dagger}c_{j} + \text{H.c.}, \]

(43)

where “thick, oriented” and “broken” links are specified in Fig. 5(a). This model can be regarded as triangles with $\pi$-flux, coupled by weak hopping $t'$. To obtain a lower bound for the ground-state energy of bosons and an upper bound for that of fermions, the Hamiltonians are written as $\mathcal{H} = \sum_{\vec{k}} \tilde{E}_{\vec{k}}^F - A$ and $\mathcal{H} = \sum_{\vec{k}} \tilde{E}_{\vec{k}}^B + B$ with the same definitions of $A$ and $B$ in Eqs. (34)-(35), where $\tilde{E}_{\vec{k}}^F = -t \sum_{i=1}^{3}(e^{i\pi/3}c_i^{\dagger}c_{i+1} + \text{H.c.}) + 2t' \sum_{i=1}^{3}c_i^{\dagger}c_i$ and $\tilde{E}_{\vec{k}}^B = -t \sum_{i=1}^{3}(e^{i\pi/3}c_i^{\dagger}c_{i+1} + \text{H.c.}) - 2t' \sum_{i=1}^{3}c_i^{\dagger}c_i$, the cluster Hamiltonians defined on a solid-line pointing up triangle. Therefore, we have $E_0^{B} \geq \sum_{\vec{k}} \tilde{E}_{\vec{k}}^B$, $\tilde{E}_{\vec{k}}^F \leq \sum_{\vec{k}} \tilde{E}_{\vec{k}}^F$. The ground-state energies in given $m$-particle sectors are demonstrated in Table II. Also the number of unit cells is assumed as $N$, a lower bound for bosons is given by $E_0^{B} \geq -N(t + 4t' )$ when $t'/t \leq 1/2$ or $E_0^{B} \geq -6Nt'$ when $1/2 < t'/t < 1$. An upper bound for fermions is given by $E_0^{F}$, which also depends on the density pattern on the whole lattice. At $2/3$ filling, we find $E_0^{F} \leq -2N(t - 2t')N$. According to the results of exact diagonalization on a cluster, we find when $t'/t \leq 1/8$, $E_0^{B} \geq -N(t + 4t') \geq -2N(t - 2t') \geq E_0^{F}$.

The second approach for the ground-state energy of fermions is to calculate the dispersion. The dispersion relations are ($t=1$ is assumed):

\[ E^{(1)} = \frac{1}{2}(1 - t') - \sqrt{9(t')^2 + 6t' + 9 + 8t'\Delta(\tilde{k})}, \]

\[ E^{(2)} = t' - 1, \]

\[ E^{(3)} = \frac{1}{2}(1 - t') + \sqrt{9(t')^2 + 6t' + 9 + 8t'\Delta(\tilde{k})}, \]

where $\Delta(\tilde{k}) = \cos k_1 + \cos k_2 - \cos k_3$, $k_{1,2} = \tilde{k} \cdot \vec{a}_{1,2}$ and $k_3 = k_1 - k_2$. The ground-state energy of fermions at $2/3$ filling is given by the integral of the lowest two bands in the Brillouin zone, which is shown in Fig. 5 (c),

\[ E_0^{F} = \sum_{k_x, k_y} \left[ E^{(1)}(k_x, k_y) + E^{(2)}(k_x, k_y) \right] \]

\[ = \frac{\sqrt{3}N}{2} \int_{BZ} \frac{dk_x}{2\pi} \frac{dk_y}{2\pi} \left[ E^{(1)}(k_x, k_y) + E^{(2)}(k_x, k_y) \right], \]

(44)

where $k_{x,y} \in BZ$ as shown in Fig. 5 (b). The basis vectors $\vec{b}_1$ and $\vec{b}_2$ are chosen accordingly as $2\pi(1, -1/\sqrt{3})$ and $2\pi(0, 1/\sqrt{3})$, respectively. The reversed natural inequality holds when $t' \ll t$. For example, when $t = 1$ and $t' = 0.1$, $E_0^{B} \geq -1.4N > E_0^{F} = -2.004349N$; when $t' = 0.2$, $E_0^{B} \geq -1.8N > E_0^{F} = -2.017037N$, in which case the inequality $E_0^{B} \geq E_0^{F}$ is not reverted by weak inter-ring coupling $t'$ as expected.
is the finite-size scaling with \((\Phi_0 = \hbar c/e)\) is employed. By exact diagonalization, the ground-state energies of bosons and fermions are obtained with different particle densities and various values of flux. The energy spectra of \(4 \times 7\) and \(5 \times 6\) lattices are shown in Fig. 6. The natural inequality holds in white plaquettes and it is violated in colored regions. The energy spectra with our choice of geometry are not of particle-hole symmetry, because these lattices are not bipartite so that particle-hole symmetry is absent for fermions.

![Fig. 6](image)

**FIG. 6.** The energy density difference \(\Delta \epsilon = E_b^0/N - E_f^0/N\) between bosons and fermions on (a) \(4 \times 7\) and (b) \(5 \times 6\) square lattices, where \(n_c\) is the number of particle per site and \(\Phi/\Phi_0\) is the number of the flux quanta per plaquette.

In both examples, as expected, the reversed natural inequality still holds when the inter-ring hopping is sufficiently weak.

C. Two-dimensional system with flux

As we discussed in Sec. IV A, the energy difference between bosons and fermions on a ring is a finite-size effect, and indeed vanishes in the thermodynamic limit. This is rather natural, it is only the entire system as a ring that contains \(\pi\) flux. As a simple extension of the idea, here we consider the two-dimensional square lattice in a uniform magnetic field, described by the Hamiltonian:

\[
\mathcal{H} = - \sum_{(j,k)} (t_{jk} c_{j}^{\dagger} c_{k} + \text{H.c.}),
\]

where \(t_{jk} = t \exp(i \Phi_{jk}/\Phi_0)\) and \(t > 0\). The flux passing through every plaquette is \(\sum_{\Box} \Phi_{jk} = \Phi\). With periodic boundary condition, the total flux is quantized as an integral multiple of flux quantum (\(\Phi_0 = \hbar c/e\) is \(2\pi\) in our unit). The magnetic field introduces frustration, through the existence of complex hopping amplitudes \(t_{jk}\).

To investigate all the possible values of flux per plaquette, string gauge\(^{26}\) is employed. By exact diagonalization, the ground-state energies of bosons and fermions are obtained with different particle densities and various values of flux. The energy spectra of \(4 \times 7\) and \(5 \times 6\) lattices are shown in Fig. 6. The natural inequality holds in white plaquettes and it is violated in colored regions. The energy spectra with our choice of geometry are not of particle-hole symmetry, because these lattices are not bipartite so that particle-hole symmetry is absent for fermions.

![Fig. 7](image)

**FIG. 7.** Finite-size scaling of ground-state energies in two-dimensional square lattice with \((N/2 - 1)\Phi_0/N\) flux per plaquette at filling fraction \((N/2 - 1)/N\). The fitting functions are \(E_b^0/N = -0.7593 + 8.973/N^2 + O(N^{-4})\) for hard-core bosons and \(E_f^0/N = -0.9507 + 8.043/N^2 + O(N^{-4})\) for fermions respectively. The extrapolated groundstate energy density for fermions matches well with the exact result \(-0.958091\).

We plotted Fig. 7 to show the finite-size scalings. Figure 7 is the finite-size scaling with \((N/2 - 1)\Phi_0/N\) flux per plaquette near half filling \((N/2 - 1)/N\). The exact half filling on finite-size lattices \((N/2\) particles on \(N\) sites) and the corresponding \(\Phi_0/2\) flux per plaquette are avoided to reduce the strong finite-size effect (oscillatory behavior) due to commensuration, while the extrapolation corresponds to the half filling in the thermodynamic limit. The extrapolation suggests that the fermions have a lower ground-state energy in the thermodynamic limit. Actually, we can prove\(^7\) rigorously in the following that this is indeed the case. Let us discuss the square lattice with \(\pi\)-flux per plaquette, described by the Hamiltonian (45). For convenience, we choose the gauge so that the hopping amplitude \(t_{jk}\) is \(+1\) on the black links, and \(-1\) on the blue ones as shown in Fig. 8 (a). By taking a \(2 \times 2\) unit cell (which is twice as large as the minimal magnetic unit cell), the dispersion relation is \(E_{\pm} = \pm \sqrt{4 + 2 \cos 2k_x - 2 \cos 2k_y}\), where \((k_x, k_y)\) is the wavenumber which belongs to the reduced Brillouin zone \(-\pi/2 \leq k_x, k_y < \pi/2\). The bands in the first Brillouin
zone are shown in Fig. 8 (b). Each energy level is doubly degenerate. The ground-state energy of fermions at zero chemical potential, which corresponds to the half filling, is given as $E_0^f = \sum_{k_x,k_y} 2E_f(k_x,k_y)$, where the factor 2 comes from the double degeneracy. For the square lattice of size $L_x \times L_y (N = L_x L_y)$, $k_{x,y}$ is respectively quantized as integral multiples of $2\pi/L_{x,y}$. Thus, in the thermodynamic limit $L_{x,y} \to \infty$, the ground-state energy of the fermionic model at $\mu = 0$ is obtained exactly as

$$E_0^f = \frac{1}{N} \int_{-\pi}^{\pi} \frac{dk_x}{2\pi} \int_{-\pi}^{\pi} \frac{dk_y}{2\pi} \sqrt{4 + 2\cos k_x - 2\cos k_y} = -0.958091.$$  \tag{46}$$

The extrapolated ground-state energy density of fermions from finite-size scaling in Fig. 7 matches well with the exact result.

We consider the grand canonical ground-state energy of bosons at the same chemical potential ($\mu = 0$). We rewrite the Hamiltonian $\mathcal{H} = \sum_\alpha h_\alpha$, where $h_\alpha = -\frac{1}{2} \sum_{(j,k) \in \mathcal{C}} \langle t_{jk} c_j^\dagger c_k + \text{H.c.} \rangle$ is the cluster Hamiltonian defined on a 12-site cross-shapped cluster as shown in Fig. 8 (a). The whole lattice is covered by the brown cross-shaped clusters with the same pattern of hopping amplitudes within the cluster, whose centers are denoted by the black dots. Therefore, each cluster overlaps with 4 neighboring clusters and each link appears in two different clusters when periodic boundary conditions are imposed. The factor $1/2$ in $h_\alpha$ compensates this double counting. By the Anderson’s argument\cite{Anderson1967, Haldane1983, Scalapino1979}, the ground-state energy $E_0^B$ of $\mathcal{H}^B$ satisfies $E_0^B \geq \sum_\alpha \epsilon_\alpha^B$, where $\epsilon_\alpha^B$ is the ground-state energy of $h_\alpha$. The ground-state energy of $h_\alpha$ on a cluster with a given particle number $m$ is shown in Table III. The results are obtained by exact diagonalization. The grand canonical ground-state energy of the cross-shaped cluster is obtained as $\epsilon_\alpha^B = -3.609035$. Assuming the number of sites in the square lattice is $N$, we obtain

$$E_0^B/N \geq -3.609035/4 = -0.902259 > E_0^F/N, \quad (47)$$

where $N/4$ is the number of clusters. Thus hard-core bosons have a higher ground-state energy than fermions at half filling ($\mu = 0$), even in the thermodynamic limit, as expected from extrapolation from finite-size scaling and statistical transmutation argument\cite{Anderson1967, Haldane1983, Scalapino1979, Sorella1993, Sorella1994}.

For other values of flux per plaquette or filling fraction, there is no rigorous proof available at present. However, the finite-size scaling of numerical data with $\Phi_0/4$ flux per plaquette at quarter filling, shown in Fig. 9, suggests that fermions have a lower ground-state energy in the thermodynamic limit.

![FIG. 9. Finite-size scaling of ground-state energies in two-dimensional square lattice with $\Phi_0/4$ flux per plaquette at quarter filling. The fitting functions are $E_0^B/N = -0.5877 - 3.405/N^2 + O(N^{-4})$ for hard-core bosons and $E_0^F/N = -0.6853 - 4.125/N^2 + O(N^{-4})$ for fermions, respectively.](image)

### D. Cluster decomposition in flat band models

In this section, we present a rigorous proof that the reversed inequality still holds in several flat-band models, even in the thermodynamic limit. Although the existence of a flat band is neither a necessary nor sufficient
condition to violate Eq. (1), it does tend to help: when
the lowest flat band is occupied by the fermions, there
is no extra energy gain due to Pauli exclusion principle.
Therefore, the inversion of the natural inequality has a
better chance to be realized in flat band models. Here
we show that the inequality (1) is indeed violated in a
few examples with flat bands, by a cluster decomposi-
tion technique.

First we discuss the delta-chain model, for which the
violation of Eq. (1) was numerically found for small clusters\textsuperscript{31,32}. The Hamiltonian of the model can be written
in the following form\textsuperscript{33,34}:

$$\mathcal{H} = \sum_{j=1}^{N} a_{j}^\dagger a_{j}, \quad (48)$$

where the $a$-operator, which acts on each triangle, is
defined as $a_{j} = c_{2j-1} + \sqrt{2}c_{2j} + c_{2j+1}$. Periodic boundary
condition is used to identify $c_{2N+1}$ with $c_{1}$. The Hamiltonian $\mathcal{H}$ corresponds to a model with negative hopping amplitudes $t_{jk}$(as defined in Eq. (2)), which lead to frustration.

The model in the single-particle sector has two bands.
The lower flat band with zero energy is spanned by states annihilated by $a_{j}$'s. We note that the Hamiltonian (48) is modified from that in Ref. 31 by a constant chemical potential, so that the flat band has exactly zero energy. Thus the ground-state energy of the fermionic version of the model (48) is zero as long as the filling fraction $\nu$ satisfies $\nu \leq 1/2$.

On the other hand, in general, construction of the ground state of a system of many interacting bosons is not straightforward even if the single-particle states are known exactly. However, the flat band in the geometrically frustrated antiferromagnet also implies the existence of non-overlapping localized zero-energy states. It was first pointed out in Ref. 35, and was later applied to various problems\textsuperscript{36,37}. In the case of the delta chain, the ground-state energy $E_{0}^{B}$ of bosons is zero as long as $\nu \leq 1/4$, since each boson can occupy different non-overlapping localized zero-energy states\textsuperscript{35,37}.

Now let us derive a nontrivial lower bound for $E_{0}^{B}$ for filling fractions $\nu > 1/4$. We decompose the model into clusters, each containing $p$ unit cells:

$$\mathcal{H} = \sum_{n=0}^{N/p-1} \mathcal{H}_{n}^{(p)} + \sum_{n=1}^{N/p} a_{np}^\dagger a_{np}, \quad (49)$$

where $\mathcal{H}_{n}^{(p)} = \sum_{j=1}^{N/p} c_{np+j}^\dagger c_{np+j}$ is the Hamiltonian for the solid triangles as in Fig. 10. Since the second term

FIG. 10. An example of decomposition of the delta-chain Hamiltonian to clusters, with $p = 4$ unit cells including one decoupled site at the top of the dashed triangle.

\[ \sum_{n=1}^{N/p} a_{np}^\dagger a_{np}, \] describing hoppings on dashed triangles, is positive semidefinite, the ground-state energy $\tilde{E}_{0}^{B}$ of the first term $\tilde{H} = \sum_{n=0}^{N/p-1} \mathcal{H}_{n}^{(p)}$ satisfies $\tilde{E}_{0}^{B} \leq E_{0}^{B}$. $\tilde{H}$ is a sum of mutually commuting cluster Hamiltonians $\mathcal{H}_{n}^{(p)}$. Thus $E_{0}^{B}$ is simply given by the sum of the ground-state energies of all clusters. The particle number within each cluster is also conserved separately in $\mathcal{H}$. Let us choose $p = 4$ as in Fig. 10, so that the cluster contains 8 sites. The ground-state energy in each sector with fixed particle number $m$ is obtained by exact diagonalization of the 8-site cluster. The results are shown in Table IV. We find $\epsilon_{0}^{(4)}(m) \geq \Delta_{DC}^{(4)} = 0.372605$ for $4 \leq m \leq 8$, while $\epsilon_{0}^{(4)}(m) = 0$ for $0 \leq m \leq 3$.

| $m$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|-----|---|---|---|---|---|---|---|---|
| $\epsilon_{0}^{(4)}(m)$ | 0 | 0 | 0 | 0.372605 | 1.838145 | 4.323487 | 8 | 12 |

TABLE IV. Ground-state energy $\epsilon_{0}^{(4)}(m)$ of the cluster Hamiltonian $\mathcal{H}_{n}^{(4)}$ for delta-chain, with $m$ particles in a cluster. The cluster contains 8 sites, as shown in Fig. 10.

If we consider the filling fraction in the range $3/8 < \nu \leq 1/2$, it follows from Dirichlet’s box principle that there is at least one cluster which contains 4 or more particles. Thus, in this range, $E_{0}^{B} \geq \Delta_{DC}^{(4)}$ for any system size $N$, while $E_{0}^{B} = 0$. Therefore, the inversion of the ground-state energies holds also in the thermodynamic limit.

The outcome of the above argument depends on the cluster size taken. In fact, the range of filling fraction $\nu$ for which we have proved the violation of Eq. (1) is not optimal. In Sec. IV.E, using a different technique, we will extend the range to $1/4 < \nu \leq 1/2$; the lower bound 1/4 is in fact optimal.

This method can be easily extended to other lattices. For example, the standard nearest-neighbor hopping model on the kagome lattice can be written as

$$\mathcal{H} = \sum_{\alpha} a_{\Delta_{\alpha}}^\dagger a_{\Delta_{\alpha}} + \sum_{\alpha} a_{\triangledown_{\alpha}}^\dagger a_{\triangledown_{\alpha}}, \quad (50)$$

where $\Delta_{\alpha}$ and $\triangledown_{\alpha}$ are elementary triangles pointing up and down, respectively, of the kagome lattice, as shown in Fig. 11. We define $a_{\Delta_{\alpha}} \equiv c_{\alpha_{1}} + c_{\alpha_{2}} + c_{\alpha_{3}}$, where $\alpha_{1,2,3}$ refer to the three sites belonging to $\Delta_{\alpha}$, and likewise for

FIG. 11. The 12-site clusters of “Star of David” shape are shown in solid lines on kagome lattice.
TABLE V. The lowest energies of cluster Hamiltonian \( H_{\text{cluster}} \) on 12-site “Star of David” shape, in sectors with different numbers of particles \( m \).

| \( m \) | \( E_{\text{cluster}}(m) \) |
|---|---|
| 1 | 0 |
| 2 | 0 |
| 3 | 0 |
| 4 | 0.311475 |
| 5 | 0.937767 |
| 6 | 1.706509 |
| 7 | 3.365207 |
| 8 | 5.196963 |
| 9 | 7.156468 |
| 10 | 9.385433 |
| 11 | 14 |
| 12 | 18 |

\( a_{\gamma n} \). The fermionic version of the model has three bands, the lowest of which is a flat band at zero energy\(^{35,36,38,39} \). Thus \( E_F^0 = 0 \) when \( \nu \leq 1/3 \).

For the ground-state energy of the bosonic version, we can use the cluster decomposition technique similar to what we have discussed above for the delta-chain. Let us choose the 12-site cluster of the “Star of David” shape, which is shown by solid lines in Fig. 11. The ground-state energy of the cluster in each sector with \( m \) particles is shown in Table V. The ground-state energy \( e_0^\text{cluster} \) of each cluster is zero with \( m \leq 3 \), but is positive with \( m \geq 4 \). Thus, invoking Dirichlet’s box principle again, Eq. (1) is violated for filling fraction \( 1/4 < \nu \leq 1/3 \). This conclusion also holds in the thermodynamic limit, where the system size \( N \) is taken to the infinity while keeping the filling fraction \( \nu \) constant.

E. Optimal lower bound of filling fraction of the violation in delta-chain model

Let us improve the estimate of the range of the filling fraction, for which the violation of Eq. (1) occurs on the delta-chain. Our result is that the violation occurs, namely the reversed inequality \( E_0^\text{B} > E_0^\text{F} \) holds, for \( 1/4 < \nu \leq 1/2 \). In fact, in this range of filling, the ground-state energy of bosons is strictly positive while the ground-state energy of fermions is zero.

To prove this, consider Bose-Hubbard model (without hard-core constraint) with finite on-site \( U > 0 \) in the enlarged Hilbert space first,

\[
\mathcal{H} = \mathcal{H}_{\text{hop}} + \mathcal{H}_{\text{int}},
\]
\[
\mathcal{H}_{\text{hop}} = \sum_{j=1}^{N} a_j^\dagger a_j,
\]
\[
\mathcal{H}_{\text{int}} = \frac{U}{2} \sum_{i=1}^{2N} n_i(n_i - 1),
\]

where \( n_i = c_i^\dagger c_i \), and \([c_i, c_j^\dagger] = \delta_{ij}\) for bosons. The definition of \( a \)-operator is the same as \( a_j = c_{2j-1} + \sqrt{2}c_{2j} + c_{2j+1}\). The hard-core constraint can be implemented by taking \( U \to \infty \), and this problem is reduced to equation (48) in this limit.

Obviously, the hopping term \( \mathcal{H}_{\text{hop}} \) is positive semi-definite. The on-site interaction, \( \mathcal{U} \) term, is also positive semi-definite because \( \frac{U}{2}n_i(n_i - 1) = \frac{U}{2}c_i^\dagger c_i c_i^\dagger c_i \) for bosons. As a consequence, all the energy eigenvalues cannot be negative. Therefore, any state with \( E^B = 0 \) is a ground state. If such a ground state \( |\Phi_{\text{GS}}\rangle \) exists, it satisfies

\[
|\Phi^B_{\text{GS}}\rangle = \sum_{\{n_1, \ldots, n_N\}} f(n_1, \ldots, n_N)(b_1^\dagger)^{n_1}(b_2^\dagger)^{n_2} \cdots (b_N^\dagger)^{n_N}|0\rangle,
\]

namely \( |\Phi_{\text{GS}}\rangle \) a simultaneous zero-energy ground state of \( \mathcal{H}_{\text{hop}} \) and \( \mathcal{H}_{\text{int}} \). Therefore, we first seek zero-energy ground states of \( \mathcal{H}_{\text{hop}} \) and \( \mathcal{H}_{\text{int}} \), separately.

Consider the zero-energy ground state of \( \mathcal{H}_{\text{hop}} \) first. Define \( b \)-operator as \( b_j = c_{2j} - \sqrt{2}c_{2j+1} + c_{2j+2} \). Because \( b \)-operators commute with any \( a \)-operator, \( [a_i, b_j] = 0 \) for any \( i \) and \( j \), the single-particle flat band with \( E^B_0 \) is spanned by \( b_j^\dagger|0\rangle \). Note that these states \( b_j^\dagger|0\rangle \) are linearly independent but not orthogonal to each other. The zero-energy state (valley state) \( b_j^\dagger|0\rangle \) is shown in Fig. 12 by blue lines. It is the first excited state of spin-1/2 antiferromagnetic Heisenberg model near saturation field, with single magnon trapped in the valley of the delta-chain\(^{35-37} \). The current setup corresponds to the magnetic field exactly at the saturation field, so that these trapped magnons are exactly at zero energy. The ground state of \( \mathcal{H}_{\text{hop}} \) can be constructed out of \( b \)-operators as,

\[
|\Phi^B_0\rangle = \sum_{\{n_1, \ldots, n_N\}} 2n_j(n_j - 1)f(n_1, \ldots, n_N) \times (b_1^\dagger)^{n_1} \cdots (b_j^\dagger)^{n_j - 2} \cdots (b_N^\dagger)^{n_N}|0\rangle.
\]

Then the linear independence of \( b \)-operators, together with \( c_j^\dagger c_i|\Phi^B_0\rangle = 0 \), implies that \( f(n_1, \ldots, n_N) = 0 \) if there exists \( j \) such that \( n_j > 1 \). We thus restrict our attention to the case where \( n_j = 0 \) or 1 for all \( j \) in the sum. We successively find

\[
c_j^2|\Phi^B_0\rangle = \sum_{\{n_1, \ldots, n_N\}} 2n_j(n_j - 1)f(n_1, \ldots, n_N) \times (b_1^\dagger)^{n_1} \cdots (b_{j-1}^\dagger)^{n_{j-1}}(b_j^\dagger)^{n_j - 1} \cdots (b_N^\dagger)^{n_N}|0\rangle.
\]
where \( n_j = 0 \) or \( 1 \) has been applied. From the linear independence of \( b \)-operators and \( c_{ij}^2 |\Phi_0^B\rangle = 0 \), we see that \( f(n_1, \ldots, n_N) = 0 \) if there exists \( j \) such that \( n_j n_{j-1} \neq 0 \). This implies that, for bosons, in the construction of the zero-energy ground state, \( b \)-operators on adjacent valleys cannot be applied on the vacuum \( |0\rangle \). Thus, the zero-energy ground states are in one-to-one correspondence with particle configurations in one-dimensional chain with nearest neighbor exclusion. This mapping is schematically shown in Fig. 12. In the range \( \nu \leq 1/4 \), we can find a particle configuration that satisfies the exclusion rule. However, in the case \( \nu > 1/4 \) we cannot find such configuration, implying the absence of zero-energy state.

The zero-energy ground states remain as ground states for any \( \mathcal{U} > 0 \), and hence in the limit \( \mathcal{U} \to \infty \). Since the on-site \( \mathcal{U} \) term is positive semi-definite, no state joins the zero-energy sector with increasing \( \mathcal{U} \). Therefore, the ground-state energy of hard-core bosons (corresponding to \( \Phi = 0 \)) is strictly positive in the range of filling \( \nu > 1/4 \).

On the other hand, for fermions, \( \{a_i, b_j^\dagger\} = 0 \) holds for any \( i \) and \( j \). The zero-energy state for fermions in the range of filling fraction \( \nu \leq 1/2 \) can also be constructed by \( b \) operators,

\[
\Phi_0^F = \sum_{\{n_1, \ldots, n_N\}} f(n_1, \ldots, n_N) (b_1^\dagger)^{n_1} (b_2^\dagger)^{n_2} \cdots (b_N^\dagger)^{n_N} |0\rangle,
\]

where \( n_j = 0, 1 \). It is easy to confirm that this is the zero-energy state of \( \mathcal{H} \) because \( \mathcal{H}_{\text{hop}} |\Phi_0^F\rangle = 0 \) and \( \mathcal{H}_{\text{int}} \) vanishes. We conclude the reversed inequality \( E_0^B > E_0^F \) holds in the range \( 1/4 < \nu \leq 1/2 \).

From the above analysis, it also follows that both bosonic and fermionic systems have exactly zero-energy ground states for \( \nu \leq 1/4 \). Thus the lower bound of the range of the filling fraction for the reversed inequality to hold, \( 1/4 \), is in fact optimal.

An argument similar to the above for delta-chain model can be employed for kagome lattice, to extend the range of filling fraction where the natural inequality is violated. The zero-energy states for kagome lattice are in one-to-one correspondence with uncontractible cycle sets on the honeycomb lattice, as defined in Ref. 40. It can then be deduced that the zero-energy states exist for \( \nu \leq 1/9 \). The uncontractible cycle sets are given by close-packed hard hexagons\(^{35,36,40} \) at the critical value \( \nu = 1/9 \), and do not exist for \( \nu > 1/9 \). Therefore, the range of filling fraction in which \( E_0^B > E_0^F \) holds on kagome lattice, is extended to \( 1/9 < \nu \leq 1/3 \).

**F. Extension to interacting systems**

Theorems 1, 2 and 3 are valid even in the presence of other interaction term besides hard-core interaction. In the remainder of the paper, we dropped the interactions for technical simplicity: fermions are then free, while bosons are subject only to the hard-core interaction. Introduction of additional density-density interactions should not essentially modify physics, as it would affect bosonic and fermionic models in a similar manner. For example, the interaction terms are introduced in diagonal terms in the matrix of Hamiltonian in Theorem 1, which do not affect the conclusion of the comparison. Therefore, in order to understand the essence of physics in the present problem, it would suffice to consider the models without interactions other than the hard-core interaction.

That said, in fact, one can actually prove that the inequality (1) is violated even in the presence of an additional interaction, in the one-dimensional ring with \( \pi \) flux discussed in Sec. IV A. This can be seen by noting that Jordan-Wigner transformation applies regardless of the presence of interaction (the number of particles is assumed to be even),

\[
E_0^B (\Phi = \pi) = E_0^B (\Phi = 0),
\]

\[
E_0^F (\Phi = 0) = E_0^F (\Phi = \pi).
\]

Then we see that a lattice version of Simon’s theorem\(^{19} \) also applies in the presence of the interaction:

\[
E_0^B (\Phi = \pi) \geq E_0^B (\Phi = 0),
\]

giving \( E_0^B (\Phi = \pi) \geq E_0^F (\Phi = \pi) \). Furthermore, under appropriate assumptions, it is possible to prove the strict inequality \( E_0^B (\Phi = \pi) > E_0^F (\Phi = \pi) \) in the presence of interaction, with an argument similar to the proof of Theorems 1 and 4.

**V. CONCLUSIONS AND DISCUSSIONS**

In this paper, we have proved that the ground-state energy of hard-core bosons is lower than that of fermions if there is no frustration in the hopping.

The effect of the statistical phase of fermions can then be understood as a frustration, since it results in destructive quantum interferences among different paths. In fact, the phase introduced by Fermi statistics can be effectively described by a magnetic flux, after the mapping to the single-particle tight-binding model on a fictitious lattice which represents the Fock space. In this sense, the non-strict version of the natural inequality is a corollary of the lattice version of the diamagnetic inequality. On
the other hand, we also proved a strict version of the natural inequality, under certain conditions. The key to the proof is the contribution of an exchange process of two particles, which is exactly what demonstrates the statistics of the particles. The argument is used to prove the strict version of the diamagnetic inequality on the lattice.

Once a magnetic flux is introduced in the original many-particle problem, the hopping terms can be frustrated. The hopping frustration can partially cancel the statistical frustration of fermions, hinting at the possibility that the natural inequality can be reversed in the presence of hopping frustration. We proved rigorously that the natural inequality is indeed reversed in the presence of frustration, in various examples. They include one-dimensional π-flux ring, coupled rings in two dimensions, two-dimensional square lattice with flux, flat band models by cluster decomposition technique. By means of the theory of flat band ferromagnetism and antiferromagnets near the saturation field, we have found an improved estimate of the range of filling fraction, in which the violation of the natural inequality occurs on the delta-chain and kagome lattice. In particular, the lower bound of the range is proved to be optimal. Finally, we demonstrated an example of the violation of natural inequality with other interaction than hard-core constraint.

In this paper, we focused on the case of hard-core bosons for simplicity. However, Theorems 1, 2 and 3 can be readily generalized to soft-core bosons. This is because hard-core bosons can be regarded as a special limit of more general interacting bosons. That is, we can introduce the on-site interaction $U \ni n_i(n_i - 1)$; the hard-core constraint can be then implemented by taking $U \rightarrow +\infty$. The on-site interaction term is positive semi-definite for bosons, if $U \geq 0$. Thus the hard-core bosons have a higher ground-state energy than that of soft-core bosons at finite $U$. This implies the applicability of Theorems 1, 2 and 3 to the soft-core bosons.

Our analysis of the hard-core boson model also suggests that the natural inequality for soft-core bosons could be reversed by introducing the hopping frustrations. However, soft-core bosons are closer to free bosons, which never violate the natural inequality because of the simple argument based on perfect BEC. Thus the violation would be more difficult to be realized in soft-core bosons, compared to the hard-core bosons discussed in this paper. Other open problems include comparison in the presence of other degrees of freedom such as the orbital/flavor of particles.

In this paper, we have also discussed briefly the comparision of the ground-state energies of spinful bosons and fermions. The natural inequality still holds in the absence of hopping frustration. Although we did not discuss explicitly for spinful particles, the natural inequality is expected to be violated by introducing appropriate hopping frustration.

Here it should be recalled that, physical magnetic field not only introduces phase factors in hopping terms, but is also coupled to the spin degrees of freedom via Zeeman term. Thus, Zeeman term should be also taken into account, in order to discuss a physical magnetic field applied to the system of charged particles. The Zeeman term acts as different chemical potentials for up-spin and down-spin particles. Thus much of the discussion in the present paper is still applicable. For example, in the absence of hopping frustration, the natural inequality still holds even in the presence of the Zeeman term. Once hopping frustration is introduced, the natural inequality can be violated. However, exactly how the violation of the natural inequality occurs does depend on the chemical potential, and on the Zeeman effect in the case of spinful particles.

On the other hand, we also note that phase factors in hopping terms and Zeeman coupling are two distinct effects, which in principle can be controlled independently. In fact, for neutral cold atoms, the phase factor in hoppings are usually introduced as “synthetic gauge field”\textsuperscript{41}, instead of the physical magnetic field. This does not produce Zeeman coupling, making it possible to study the effect of hopping frustrations separately from that of the Zeeman effect.

VI. ACKNOWLEDGEMENT

We are grateful to Ehud Altman, Claudio Chamon, Sebastian Huber, Fumihiko Nakano, Xiwen Guan, Naoki Kawashima, Naomichi Hatano and Hui-Hai Zhao for the valuable discussions and comments. W.-X. N. thanks MEXT scholarship. M. O. was supported in part by MEXT Grant-in-Aid for Scientific Research on Innovative Areas (KAKENHI) Nos. 20102008 and 25103706, while H. K. was supported in part by JSPS Grant-in-Aid for Young Scientists (B) (KAKENHI) No. 23740298. A part of the present work was carried out during a visit of W.-X. N. and M. O. to Kavli Institute for Theoretical Physics, UC Santa Barbara, supported by US National Science Foundation Grant No. NSF PHY11-25915. Part of the numerical calculation is carried out by TITPACK ver.2, developed by H. Nishimori.
