Tracing the precise developmental origin of amnion and amnion-derived stem cells is still challenging and depends chiefly on analyzing powerful genetic model amniotes like mouse. Profound understanding of the fundamental differences in amnion development in both the disc-shaped primate and human embryo and the cup-shaped mouse embryo is pivotal in particular when sampling amniotic membrane from nonprimate species for isolating candidate amniotic stem cells. The availability of molecular marker genes that are specifically expressed in the amniotic membrane and not in other extraembryonic membranes would be instrumental to validate unequivocally the starting material under investigation. So far such amniotic markers have not been reported. We postulated that bone morphogenetic protein (BMP) target genes are putative amniotic membrane markers mainly because deficiency in one of several components of the BMP signaling cascade in mice has been documented to result in defective development of the early amnion. Comparative gene expression analysis of acknowledged target genes for BMP in different extraembryonic tissues, combined with in situ hybridization, identified Periostin (Postn) mRNA enrichment in amnion throughout gestation. In addition, we identify and propose a combination of markers as transcriptional signature for the different extraembryonic tissues in mouse.

1. Introduction

The amnion is the innermost extraembryonic membrane that surrounds the foetus of amniotes and delineates the fluid-filled amniotic cavity, thereby providing a confined environment within the conceptus and conferring protection and shock resistance. In most amniotes, the amnion is a thin and avascular transparent membrane. In recent years, human term amnion has attracted considerable attention because amniotic-ectoderm- and mesoderm-derived cells can differentiate into cells from the three germ layers in cell culture. Furthermore, resident stem cell-like cells in the amniotic ectoderm have been reported (reviewed in [1, 2], this issue). In addition, the low immunogenicity of the amnion makes this “medical waste” tissue of great interest for (regenerative) medicine. Indeed, the amnion has been used for over a century as a wound dressing.

Recently, studies aiming to explore the presence and origin of amniotic stem cells have been accomplished, using much more powerful genetic model organisms, such as, mouse and rat. Despite the fundamental differences in amnion development in the disc-shaped primate embryo and in the cup-shaped mouse embryos (for review: [2]), amniotic-membrane and amniotic-fluid derived cells with stem-cell-like features have been isolated from mouse and rat [3, 4].

In human, both amnion and chorion surround the embryo and both membranes fuse during the second trimester of pregnancy, while the yolk sac remains rudimentary [2]. In contrast, in mouse, the chorion will never fuse with the amniotic membrane after the physical separation of the amniochorionic fold shortly after gastrulation at embryonic day (E)7.0 [6]. The chorion becomes incorporated in the chorionic disk of the placenta, whilst the amnion
becomes surrounded by the visceral yolk sac, except in the part of the chorionic disk. Importantly, amnion on the one hand and yolk sac and chorionic disk on the other hand remain spaced by the fluid-filled exocoelomic cavity (Figures 1(a)–1(c)). In mouse embryos, the amnion consists throughout gestation of a simple bilayered membrane of squamous mesoderm and ectoderm, which face the exocoelomic and amniotic cavity, respectively.

Awareness of the fundamental different surrounding tissues of human and mouse amnion is important when collecting amniotic membrane from nonprimate species to isolate the so-called amniotic stem cells [2]. The availability of molecular markers that are specifically present in amnion and not in the other extraembryonic membranes, or in the respective fluids, would therefore be helpful to characterize unequivocally the initial starting material from which stem cells are isolated.

Spatial gene expression studies rarely include information on expression in amnion, in part because this tissue appears prone to be neglected or discarded, but also because it is often hard to distinguish low expression levels from background staining due to the flat cellular architecture of this stretched membrane. To our knowledge, amnion-specific genes have not explicitly been reported, but the physiologic features of the amnion may hint towards putative candidate amnion markers. The amnion is a very elastic tissue that resists to increasing stretch. Hence, progressively, a basal lamina composed of collagen, laminin, nidogen, and fibronectin fibers forms between the amniotic ectoderm and mesoderm [7, 8]. The amniotic epithelium acquires
Figure 2: RNA profiling of putative amnion markers in mouse extraembryonic tissues by RT-qPCR. (a)–(b) Validation of microdissected amniotic membrane tissues collected at different stages of development by relative RNA expression analysis of markers for (a) nonneural ectoderm (Ap-2) and allantois (Tbx4) and (b) primitive red blood cells (ζ-globin) and yolk sac endoderm (Afp). (c)–(e) Expression analysis of acknowledged target genes of SMAD-mediated BMP signaling (Tbx2, Tbx5, Hand1, Hand2, Msx1, Msx2) and (f) Postn, in extraembryonic tissues. Relative RNA levels were obtained by setting the sample with lowest expression for each target to 1. The expression of different targets cannot be directly compared. Abbreviations: Am: amnion; Al: allantois; YS: yolk sac.

an increasing number of microvilli at the surface, which may be associated with enhanced filtering and transport capacity across the membrane. Mouse models with impaired amnion development may also tip-off candidate amnion markers. Remarkably few mouse mutants displaying defects in amnion formation have been described (reviewed in [6]), in contrast to the many mutants with defects in allantois [9] or placenta [10]. Many of the mutants that display defects primarily related to amnion development seem to point at impaired bone morphogenetic protein (BMP) signaling (Bmp2, Smad5) or are found in genes that encode putative modulators of BMP signaling (Amn, Bmp1). Amnionless

**Figure 4:** (a) RNA profiling of *POSTN* in human extraembryonic tissues of three individual embryos by RT-qPCR. Gestational age is represented by weeks (w) and days (d). (b) Relative RNA expression of *Postn/POSTN* in mouse and human amnion samples from different developmental stages. In human amnion *POSTN* is expressed at very high levels during the first trimester, followed by a significant drop in expression, whilst *Postn* expression in mouse amnion is stable during gestation. Mouse and human developmental stages are positioned along an arbitrary interval scale. Mouse and human gestation approximates 19.5 days and 38 weeks respectively. Mouse and human developmental stages do not match pairwise. Abbreviations: Am: amnion; Ch: chorion, E: embryonic day; Pl: placenta, UC: umbilical cord, 8–38 w: weeks of gestation.
sac. and Postn are neglectable. In contrast, yolk sac and allantois express low levels of Postn. Amnion is enriched in different transcripts with different expression levels in a single graph. Expression levels of different genes cannot be compared. Amnion is enriched in Postn and AP-2, while visceral yolk sac (Afp), allantois (Tbx4), and primitive red blood cell (ζ-globin) markers are neglectable. In contrast, yolk sac and allantois express low levels of Postn and AP-2. (Ann) mutants develop the most specific defects because they lack an amnion, whereas chorion, yolk sac blood islands, and allantois develop normally [11]. Bmp2 null embryos fail to close the amnion [12]. Mice deficient in Smad5, an intracellular mediator of BMP signaling, also show delayed amnion closure, in addition to local amnion thickenings that contain ectopic stem cell-like cells, haematopoietic and endothelial cells [13–15]. Several ligands may elicit BMP signaling in amnion. Bmp4 is expressed abundantly in mouse amnion, but Bmp2 and Bmp7 transcripts have also been reported in amnion and adjacent tissues [16–18].

The crucial role for BMP signaling in amnion development made us hypothesize that target genes for BMP are candidate markers of the amniotic membrane. Given the poor documentation of the expression of such target genes in the developing amnion and its neighboring tissues, we have performed a comparative gene expression analysis of several such target genes in different extraembryonic tissues. Transcripts for periostin (Postn) appeared to be highly enriched in mouse and human amnion at different stages of development. Periostin is a secreted ECM protein that can interact with different ECM proteins and integrins and that is induced by transforming growth factor (TGF)β and BMPs in tissues undergoing remodeling or active stress (reviewed in [19]). In situ hybridization analysis confirmed the amnion-enriched localization of Periostin mRNA in amnion. We propose to use a combination of Periostin and AP-2 as biomarkers for developing mouse amniotic membrane.

2. Materials and Methods

2.1. Collection of Mouse and Human Extraembryonic Tissues.

Wild type mouse embryos (CD1) between E8.5 and E18.5 were isolated in ice cold PBS, followed by collection of the amnion, allantois, and visceral yolk sac tissues. The material was washed in ice cold PBS and immediately frozen and stored at −80°C until further processing. BRE : LacZ embryos are transgenic for a gene composed of a BMP-responsive element (BRE) from the Id1 promotor that drives β-galactosidase synthesis that reports BMP-SMAD activity [5]. These embryos were isolated between E7.0 and E8.0 in ice cold PBS, and further processed for β-galactosidase staining. CD1 embryos were collected at E8.5 and E9.5 in ice-cold PBS, fixed in 4% paraformaldehyde in PBS and further processed for in situ hybridization (ISH).

First and second trimester human extraembryonic tissues were isolated in ice cold PBS and immediately frozen in RLT buffer (Qiagen) until further processing (LUMC). These tissues were collected from voluntary abortions without medical, fetal or obstetrical complications. Human term amnion was collected following planned cesarean sections at the Obstetrics and Gynaecology division, UZ Leuven. Collection of mouse and human tissues was approved by the ethical commission from the KU Leuven (097/2008) and by the Medical Ethical Committee of the Leiden University Medical Center (P08.087), respectively.

2.2. β-Galactosidase Activity and In Situ Hybridization.

After brief glutaraldehyde/formaldehyde fixation, BRE : LacZ heterozygous embryos were washed in PBS and stained for β-galactosidase overnight at 30°C in a staining solution of 5-bromo-4-chloro-3-indolyl-beta-D-galacto-pyranoside (X-gal, Fermentas, R0941), as described before [5]. Stained and postfixed embryos were subsequently washed, dehydrated, paraffin embedded and sectioned at 6 μm. Slides were counterstained with Mayer’s Hematoxylin.

For in situ hybridization, embryos were fixed overnight in 4% paraformaldehyde in PBS at 4°C, washed with PBS and saline, dehydrated and embedded in paraffin, and sectioned...
at 6 μm. In situ hybridization on sections with DIG-labeled antisense riboprobes against Tbx2 [20], Tbx5 [21], Msx1 [22], Msx2 [23], and Postn [24] was performed using an automated platform (Ventana Discovery, Ventana Medical Systems).

2.3. Gene Expression Analysis. RNA was extracted and purified with RNasey purification columns (Qiagen, RNasey Mini or Micro kit, 74104 and 74004). Reverse transcription was performed using SuperScript III reverse transcriptase (Life Technologies), oligo-dT and random primers (Life Technologies). Real-time qPCR was performed on LightCycler 480 Real-Time PCR System using LightCycler 480 SYBR Green I Master mix (Roche, 4707516001), and all reactions were in technical duplicates. Primers were designed with the online tool of IDT (http://www.idtdna.com/). Gapdh and Ubc (mouse) and GAPDH and β-Actin (human) were used as reference genes for normalization. Mouse primer sequences are (forward primer first) Afp: GATGAAAATATGCGCC- CCTCC, CAAAAGGCCGAAAGCATGG; Ap-2: CGTTACCCCTCAGTCTAGT, TTTCGACAGTACC-CAAAGT; Hand1: CCAAGAACGCAAAGGGGGATT, TTTAGCTCCAGCGCCCAGACTT; Tbx5: AGGCCCTTTGAAGCCAGTTC, CCTTGCCCAGCTTTTGTTTTC-TTG; Msx1: CACCTACGCAAGCACAAGA, GAGGCTGAGCTGTGTTGAA; Msx2: GCTGCCCCAGCCTTT- CAGT, TGCCGGTATATGGATGCT; Periostin: AAGGAA- AAGGTCTACACATCTCTTC, CCTTGCAATGTCAGA- GATCC; Tbx2: ATCGACAACACCCCTTTGCG, GAG- GTGGCACCGTCTAGC; Tbx4: TACAACCTTCCCAACTT- CAG, GGAGAAACGGGAAATGTAGCAGTGC; Tbx5: CAT- CAGTATCCTCAGTACCG, GTTACACGGGCGGCT- CTAGAG; ζ-globin: GCTTCAAGATCATGACCGCCGT, CGGTGGAGGCGCAGGCTACTT; Gapdh: AAGAAAG- GTTGGTGAAGCACCCGC, GCCCTCCTTGGTCAGTGGCT; Ubc: TAAAAAGACCCTCCTTGGCAG, AGACACCCT- CCCATCAGC. Human primer sequences are INVESTIN: GAAAGGTTGATAGCAAGGGAG, ATATAGTGCCT- TCTCAGGTT; GAPDH: TGCAACCACCAACTCCTTAG- GC, GGCTAGTGGACTTTGCTAGC; β-Actin: CAC- CTCTTCAATAGGCTGCTGTCG, ATAGCCAGACCT- GGATAGCAACGTAC. Periostin primers were designed to amplify all known 3 mouse and 4 human transcripts, respectively; the latter developing in the mesoderm of the visceral endoderm and primitive haematopoietic cells, respectively, the latter developing in the mesoderm of the visceral yolk sac [26, 27]. An appropriate amnion-specific marker was lacking at this stage but Ap-2 (Tfap2A) was included in the analysis, as we previously reported that this marker for nonneural surface ectoderm and neural crest cells [28] is also abundantly expressed in amniotic ectoderm [13]. This analysis showed that microdissected amniotic membrane samples were not contaminated with allantois (Figure 2(a)) or yolk sac (Figure 2(b)) tissue.

3. Results

Immediately after amnion formation the mouse amnion separates and demarcates the extraembryonic region from the embryonic region of the conceptus. At that stage the amnion does not surround the developing embryo yet (Figure 1(a)). At the early organogenesis stage the embryo undergoes an axial rotation and hence it gets enveloped by its amnion and yolk sac (Figures 1(b)–1(c)). Mouse amniotic membrane is composed of amniotic ectoderm in continuity with the embryonic ectoderm and of amniotic mesoderm sharing its borders with the mesothelium that delineates the visceral yolk sac and the allantois/umbilical cord in the most posterior part of the amnion (Figure 1(a)).

To investigate whether BMP elicits SMAD-mediated BMP signaling around and beyond the stage of amnion closure, we monitored BMP-SMAD activation in amnion of BRE: LacZ reporter embryos. These mouse embryos report the activation of expression of target genes for activated BMP-SMADs [5] (Figures 1(d)–1(h)). Before amnion closure, active BMP-SMAD signaling is most predominant in the amniotic ectoderm component of the amniochorionic fold (Figure 1(d)). After closure high BMP-SMAD signaling levels persist in both layers of the amnion, and the signaling domain starts to expand into the extraembryonic-embryonic junctional region, more specifically in anterior embryonic ectoderm and mesoderm and the most posterior embryonic mesoderm and extraembryonic mesoderm of amnion, allantois, and yolk sac (Figures 1(e)–1(h)).

Amniotic membranes and visceral yolk sacs (called from now on yolk sacs) were microdissected from E8.5, E9.5, E13.5, and E18.5 mouse embryos, covering early organogenesis, organogenesis, and preterm stages of development. In addition, allantoises were isolated from E8.5 and E9.5 embryos. Tissues from at least five embryos were pooled for the E8.5 and E9.5 samples, whilst tissues from older gestational stages were processed individually, and then mRNA was isolated and cDNA synthesized. To assess the quality of these samples, the expression of transcripts enriched in different extraembryonic tissues was evaluated by quantitative reverse transcription-PCR (RT-qPCR). Tbx4 was used as an allantois-specific marker [25], and Afp and ζ-globin markers of the visceral endoderm and primitive haematopoietic cells, respectively, the latter developing in the mesoderm of the visceral yolk sac [26, 27]. Identically the same amnion, visceral yolk sac, and allantois samples were profiled by RT-qPCR for the expression of 7 selected BMP targets (Tbx2, Tbx5, Hand1, Hand2, Msx1, Msx2 and Postn) as a first selection criterion for identification of a putative amnion marker(s).

The transcript levels of the T-box transcription factor encoding gene Tbx2 are high in allantois and yolk sac.
when compared to the amnion (Figure 2(c)). The expression in the allantois seemed most predominant at E8.5 and correlates with the expression domain that has been reported previously by in situ hybridization [29]. This differential enrichment in the allantois becomes unlike the Tbx4 mRNA expression—progressively lost from E9.5 onwards. The expression domain of Tbx5 has been documented by in situ hybridization in the allantois of E7.5 embryos [30]. The Tbx5 profiling does not result in a stable and robust pattern of expression in the different extraembryonic tissues (Figure 2(c)). Hence, we consider neither Tbx5 nor Tbx2 as candidate markers for amniotic membrane.

Hand1 and Hand2 encode basic helix-loop-helix transcription factors that are essential for heart and extraembryonic development [31], with Hand1 seemingly as the favorable candidate marker for amnion (Figure 2(d)). However, in addition to robust expression in the amnion [32] high expression of Hand1 has been demonstrated in the yolk sac of a Hand1: LACZ-reporter mouse strain [31]. Moreover, Hand1-deficient embryos show defects in yolk sac vasculature, suggesting that Hand1 is important for yolk sac development [33].

Msx1 and Msx2 are Msh homeobox-containing transcription factors involved in neural tube, heart, tooth, limb, and craniofacial development, and are reported to be immediate effectors of BMP signaling (reviewed in [34, 35]). Msx1 expression has been reported for chick amnion [36], and Msx2 mRNA was detected in human placenta [37]. This made us investigate the expression of these two genes in mouse extraembryonic tissues. RT-qPCR results showed high expression of both transcripts in amnion early during gestation but also in allantois (Figure 2(e)).

Postn encodes a poorly described extracellular matrix (ECM) protein. Its expression has been reported in heart and also in the amnion of developing embryos [14, 38], albeit its expression in the other extraembryonic tissues has not been documented. In independent experiments, Postn expression was consistently found to be enriched in amnion throughout mouse development (Figure 2(f)), but it was also detected in the yolk sac and allantois. Indeed, in situ hybridization analysis confirmed the high expression levels of Postn in mouse amnion at E8.5 and E9.5 and highlighted that expression is predominant in amniotic mesoderm (Figures 3(a)–3(b)). Postn expression was not detected in the allantois at E8.5, but expression was clearly detected in allantois/umbilical cord at E9.5. Likewise, Postn expression was only detected sporadically in mesothelium cells of the visceral yolk sac at E8.5, but Postn expression was observed throughout the mesothelium of amnion, allantois, and yolk sac at E9.5 (Figures 3(a)–3(b)).

In human, RT-qPCR analysis of three individual embryos demonstrated that POSTN gene expression is highly enriched in amnion during the first trimester of gestation, in comparison with the other extraembryonic tissues: chorion, placenta and umbilical cord (Figure 4(a)). POSTN expression in the umbilical cord was relatively high as well, similarly to the results for E9.5 mouse allantois (Figure 2(f)). Thus, POSTN may be considered as amnion marker in humans too, but it needs to be specified that its expression was only validated by RT-qPCR in isolated extraembryonic tissues (Figure 4(a)). Unlike in mouse, POSTN levels in human amnion decrease progressively during gestation (Figure 4(b)).

Postn expression is enriched in the amniotic membrane, but its expression in extraembryonic tissues is not exclusive to the amnion. To use Postn with confidence as an amnion marker we have analyzed a combination of markers for different extraembryonic tissues on extraembryonic samples of E8.5 and E9.5 mouse embryos (Figures 5(a)–5(b)). Based on these results, we conclude that the amniotic membrane is a tissue that expresses relatively high levels of Postn and Ap-2, and ignorable levels of ζ-globin, Afp and Tbx4 (Figures 5(a)–5(b)).

4. Discussion

Given that Bmp4 expression is patent in developing mouse amnion [16], that genetic mouse models deficient in several components of the BMP signaling cascade develop early amnion defects [6], and that active BMP-SMAD signaling is ongoing in amnion during early organogenesis development, we hypothesized that target genes for BMP are putative amniotic membrane markers. Based on this information, we followed an educated guess approach and identified Postn from a preset selection of 7 acknowledged BMP target genes as an amnion-enriched marker gene throughout gestation.

All selected BMP target genes were clearly expressed in mouse amniotic membrane, whereas expression of another BMP target gene, the allantois-specific marker Tbx4 [25], was indeed not detectable in amnion. The spatial-temporal expression pattern of the different selected BMP target genes followed different trends in the different extraembryonic tissues during development which suggests that they do not all belong to one synexpression group. For instance, Postn transcript levels were constantly high in amnion samples throughout gestation, whereas the Hand1 and the Msx2 transcripts appeared enriched in the amnion early during organogenesis, but this became less prominent in function of time. The spatial-temporal regionalization of the expression patterns of the respective BMP target genes suggests that the extraembryonic tissues under investigation are exposed to dynamic levels of signaling by (different) BMP morphogens and/or a different regionalization of transcriptional coactivators and repressors may result in a different transcriptional response.

Postn is a secreted ECM protein that has been related to bone and heart development as well as to cancer [19]. The protein is associated with areas of fibrosis; it can directly interact with other ECM proteins, such as fibronectin, tenasin-C, collagen I, collagen V and heparin sulfate proteoglycans. Periostin serves as a ligand for specific integrins, such as αvβ3, αvβ5 and α4β1 but interacts also with focal adhesion kinases and can thus affect the ability of cells to migrate [19, 39]. Postn is expressed in fibroblasts or in cells that adopt fibroblast-like characteristics following an injury event [19]. The extracellular and secreted nature of the Postn protein makes this a less appropriate amniotic membrane.
marker for FACS-based sorting of cells. Nonetheless, Postn is an interesting BMP target gene in the context of the highly stretched amniotic membrane. The expression of Postn has been reported to be induced by BMPs, but also by TGFβ1, and by mechanical stretch [40]. Secreted growth factors of the TGFβ and BMP families are well known for their involvement in endocardial cushion development within the embryonic heart tube. Postn mRNA has been shown to be expressed in the developing mouse embryonic and fetal heart and localizes to the endocardial cushions suggestive of a role in valvulogenesis and valvular disease [41]. Indeed, loss of Postn results in the inappropriate differentiation of mesenchymal cushion cells and valvular abnormalities via a TGFβ-dependent pathway during establishment of the mature heart [19, 40, 42, 43]. So far no amnion defects have been reported in Postn null mice. It has, however, been demonstrated recently that Postn interacts with BMP-1. This interaction probably results in enhanced deposition of BMP-1 and BMP-1-mediated proteolytic activation of lysil oxidase on the extracellular matrix, which promotes collagen cross-linking [44]. BMP-1, despite its misleading name, is not a BMP-related growth factor but a Procollagen C-proteinase. Intriguingly, mice deficient in BMP-1 do develop an amnion defect [7].

In the last few years, ECM has been recognized as an important source of regulatory signals in normal tissues and tumors (reviewed in [45]). Recent studies indicate a link between cancer stem cells and their metastatic niches. Together with another ECM protein-tenasin C-Postn plays a key role as metastasis niche component for breast-derived tumour-initiating cells that invade the lungs [46]. By enhancing Wnt and Notch signaling in cancer cells, Postn and tenasin C provide physical and signaling support for metastasis-initiating cells. Postn-deficient mice develop mammary tumors, but their ability to metastasize to the lungs is significantly diminished compared to tumors in wild-type mice. Malanchi et al. propose that the role of Postn in progression of lung metastasis is to concentrate Wnt ligands in the metastatic niche for the stimulation of stem-like metastasis-initiating cells [46]. Postn promotes tumor metastasis and facilitates invasion in the tumor microenvironment also in colorectal, pancreatic, oral, prostate, esophageal, and ovarian cancer [47–52]. Perhaps the presence of Postn in amnion may contribute to the reprogramming capacities of amniotic membrane cells in cell culture.

Postn is enriched in mouse amnion, and its expression level remains fairly constant during gestation. Postn mRNA appeared localized in the amniotic mesoderm, while the amniotic ectoderm appeared negative (Figure 3(a)). This was especially clear before embryo turning at E8.5 when amnion is less stretched. POSTN can be considered a suitable amnion marker in humans too, although its transcript levels decrease progressively during gestation. The timing of the observed decrease seems to correlate with the phase when amnion and chorion physically fuse, and it is therefore tempting to speculate that changes in mechanical stretch and pressure/contact with the chorion as compared to the previously surrounding fluid attenuates the POSTN levels in the amniotic membrane. During the first trimester of gestation, POSTN is highly enriched in human amnion comparing to the other extraembryonic tissues (chorion, placenta and umbilical cord), but it is not restricted to amnion only, as demonstrated by its expression in the umbilical cord. The expression of POSTN throughout gestation may be dynamic in different extraembryonic tissues because POSTN mRNA has been detected by in situ hybridization in the stromal cells of human term placenta [53]. In this study the authors do not report POSTN expression levels in other nonplacental extraembryonic tissues. In any case, analyzing sets of markers for human amniotic membrane instead of using a single marker gene is preferable, and more research needs to be performed in this direction.

Our in situ hybridization analysis confirms that mouse Postn is enriched in amnion during early organogenesis and highlights furthermore that it is expressed in amniotic mesoderm. However, Postn expression can be observed in mesothelium of the visceral yolk sac and allantois as well. To bypass making premature conclusions on amnion identity based on analysis of Postn expression levels only, we suggest to categorize amnion, visceral yolk sac and allantois by expression profiling of a set of different marker genes. Mouse amniotic membrane is characterized during early organogenesis by high levels of Postn and Ap-2, low levels of ζ-globin expression, and ignorable levels of Afp and Tbx4 (Figure 5). Visceral yolk sac can be classified as the tissue with high expression levels of Afp and ζ-globin, with moderate expression of Postn and Ap-2, and absence of Tbx4; whereas the allantois is characterized by high Tbx4 expression level and weak expression of Postn, Ap-2 and ζ-globin. Afp expression was undetectable in the allantois (Figures 2(b) and 5). Since ζ-globin is a marker of primitive haematopoietic cells in the yolk sac, it is not advisable to use this marker beyond early organogenesis development.

In summary, we propose using Postn and Ap-2 as a marker set enriched in mouse amniotic membrane and we propose a combination of markers as transcriptional signature for the different mouse extraembryonic tissues. The unbiased identification of additional markers, preferentially of amnion-enriched intracellular proteins and/or membrane proteins, and the use of panels of amnion markers should be further encouraged.
