Abstract

Purpose—To determine the effects of total body irradiation (TBI) dose, fractionation, and lung shielding on hematopoietic stem cell homing to the bone marrow.

Material and Methods—Bone marrow (BM) cells were extracted from tibiae and femurs of B6-GFP mice and were transplanted into B6 mice. Recipient mice had either: 1) no radiation, 2) single dose TBI at 13.6 Gray (Gy), 3) single dose TBI at 13.6 Gy with reduced lung exposure to 0.4 Gy by shielding, 4) split dose TBI at 12 Gy to twice/day over four days, or 5) split dose TBI at 12 Gy to twice/day over four days with reduced lung exposure to 0.36 Gy by shielding. The last radiation exposure preceded tail vein injection by 4–6 hours. Mice were sacrificed after 18 hours.

Results—Homing of GFP positive, lineage negative cells was not significantly improved in any irradiated group compared to control. Homing of GFP positive, lineage negative, Kit positive cells was significantly worse in all irradiated groups.

Conclusion—TBI does not improve the homing of lineage negative donor BM cells to the recipient marrow. Homing of lineage negative, Kit positive donor BM cells was significantly worse following TBI, with or without lung dose reduction.

Keywords

TBI; Lung Shielding; Dose Reduced; BID; Stem
Introduction

Bone marrow (BM) or peripheral blood stem cell transplantation (SCT) can be curative in the treatment of various human malignancies. In order for SCT to be successful, the transplanted stem cells must home to the correct location within the BM. In mouse models, irradiation has been found to alter the homing of stem cells.

In humans, evidence suggests that total body irradiation (TBI) improves post-transplant survival compared to the use of chemotherapy alone. Improved survival, however, may be mitigated by increased toxicity. In particular, lung toxicity has been shown to impact survival. One strategy to reduce pulmonary toxicity is to simply reduce the lung dose directly by utilizing lung shielding. Several studies have described an association between lung dose reduction, reduced pulmonary-related mortality and improved overall survival.

Specifically our clinical experience showed that, compared to twice daily radiation alone, twice daily, lung dose reduced TBI can improve survival in a subset of patients. Further analysis showed that this observed survival benefit of lung radiation dose reduction did not result from improved lung function.

It is known that TBI can alter homing of stem cells. We wondered if the observed survival benefit of twice daily, TBI with lung radiation dose reduction may result from altered homing of stem cells to the bone marrow. To answer this question, mouse experiments were performed to test the effect of twice daily, lung dose reduced TBI on homing of hematopoietic stem and progenitor cells to recipient bone marrow.

Materials and Methods

Animals

Normal C57BL/6 (B6) and the B6-EGFP transgenic mice were obtained from the Jackson Laboratory (Bar Harbor, ME) and were maintained at NIH animal facilities under normal care and nutrition conditions. The EGFP mice have been backcrossed to B6 for 15 generations to ensure a relatively pure B6 genetic background. Similar combinations were used by others in studying hematopoietic cell and niche interactions. All mice were used at 2–6 months of age and only male mice were used in the current study. All experiments were carried out under the aegis of a protocol approved by the National Cancer Institute Animal Care and Use Committee and were in compliance with the Guide for the Care and Use of Laboratory Animal Resource, (1996) National Research Council.

TBI and Lung Shielding

To specifically study the effects of lung shielding, we used a Therapax DXT300 X-ray irradiator (Precision X-ray, Inc., North Branford, CT) using 2.0 mm Al Filtration (300 KVp) to irradiate B6 recipients at a dose rate of 2.35 Gy/min. We divided 25 B6 recipients into five groups of five mice each: 1) CON: No irradiation control, 2) SD-NS: 13.6 Gray (Gy), single dose TBI without lung shielding, 3) SD-BLS: 13.6 Gy single dose TBI with bilateral lung shielding, 4) BID-BLS: 12 Gy TBI in fractionated dose with bilateral lung shielding, 5)

Bone Marrow Transplant. Author manuscript; available in PMC 2012 November 19.
BID-NS: 12 Gy TBI in fractionated doses without lung shielding. Lung shielding consisted of a 5 half-value layer block which reduced transmission to approximately 3% of the given dose. Fractionation, similar to the treatment of our clinical human cohort, consisted of twice daily radiation, 4 hours apart at 1.5 Gy each time over 4 days for a total of 12 Gy. In this experiment, each recipient received $14.0 \times 10^6$ EGFP BM cells.

BM cells from EGFP donors were at $28 \times 10^6$ cells/mL in IMDM. Each recipient mouse received 0.5 mL donor cells which were delivered through tail vein injection at 4–6 hours following the last radiation treatment. Recipient mice were euthanized 18 hours after cell injection and BM cells were collected and analyzed for donor hematopoietic cell homing.

**FACS Analysis and Detection of Hematopoietic Cell Homing in Recipient Mice**

BM cells were extracted from bilateral femurs and tibiae of recipient mice 18 hours after cell injection, and were filtered through a 90 µm nylon mesh. Cells were counted to calculate total BM cell recovery. All cells were stained with an antibody cocktail containing: Lin (CD3, CD4, CD8, CD11b, CD45R, Gr1, Ter119)-PE + CD34-PE-Cy5 + CD117-APC. Proportion and total number of GFP cells in each cell fraction were calculated to compute cell recovery (homing efficiency).

Procedures for flow cytometry were adapted as previously described[24]. In brief, BM cells were incubated in Geys solution (130.68 mM NH_4Cl, 4.96 mM KCl, 0.82 mM Na_2HPO_4, 0.16 mM KH_2PO_4, 5.55 mM Dextrose, 1.03 mM MgCl_2, 0.28 mM MgSO_4, 1.53 mM CaCl_2 and 13.39 mM NaHCO_3) for ten minutes on ice to lyse RBCs. After washing with a flow buffer (2.68 mM KCl, 1.62 mM Na_2HPO_4, 1.47 mM KH_2PO_4, 137 mM NaCl, 7.69 mM NaN_3, and 1% BSA), cells were incubated with antibody mixtures on ice for 30 minutes. Monoclonal antibodies for mouse CD3 (clone 145-2C11), CD4 (clone GK 1.5), CD8 (clone 53-6.72), CD11b (clone M1/70), CD45R (B220, clone RA3-6B2), CD117 (c-Kit, clone 2B8), erythroid cells (clone Ter119), granulocytes (Gr1/Ly6-G, clone RB6-8C5), and stem cell antigen 1 (Sca1, clone E13-161) were all from BD Biosciences (San Diego, CA). Stained cells were analyzed on an LSRII flow cytometer using the FACSDiv software (Becton Dickinson, San Jose, CA).

**Statistics**

Proportions of EGFP$^+$ and EGFP$^+$Lin$^-CD117^+$ cells in BM were multiplied by the total number of BM cells to calculate the total number of donor cells recovered in recipient BM as a percentage of EGFP$^+$ and EGFP$^+$Lin$^-CD117^+$ cell homing to recipient BM. Total number of BM cells per mouse was estimated assuming that one femur and one tibia contain 12.5% of total BM cells[25].

Data were analyzed using JMP Statistical Discovery software (SAS Institute Inc., Cary, NC), and were presented as mean with standard errors. A $P$ value <0.05 was considered as statistically significant.
Results

Radiation Reduces Hematopoietic Cell Homing to Host BM

Lung shielding did not improve homing of any subset of GFP positive cells to the BM of recipient mice following either the once daily or fractionated TBI—

To test the effect of lung shielding, we used X-rays to irradiate recipient mice as shown in Figure 1 with the lung-shielding shown in Figure 1B. The EGFP donor mice we used in the current study had higher levels of EGFP transgene expression in BM cells.

The top, left panel of Figure 2 demonstrates that 4% of recovered cells were lineage negative. The top right panel shows that 31% of the lineage negative cells were also Kit+. The lower 2 panels show that 98% of Lin− cells and 99% of Lin−Kit+ BM cells from EGFP donor mice were positive for EGFP expression, the marker used to track cells in the recipient BM.

Homing of total GFP positive BM cells (Figure 3, top), lineage negative GFP positive BM cells (Figure 3, middle), and lineage negative Kit positive GFP positive BM cells (Figure 3, bottom panel) was not significantly improved in any irradiated group compared to control. Homing of GFP positive, lineage negative cells was not improved by single dose or fractionated TBI. In fact, fractionated radiation therapy showed a 2 to 5 fold decrease in donor hematopoietic cell homing compared to single dose radiation (Figure 3).

As shown in the bottom panel of Figure 3, homing of GFP positive, lineage negative, Kit positive cells was significantly worse in all irradiated groups. Fractionated radiation therapy showed a 5 fold decrease in homing compared to single dose radiation. With either single dose or fractionated doses, lung shielding showed no beneficial effect for donor hematopoietic cells homing to recipient BM.

Discussion

This is the first study to show that lung shielding does not significantly alter homing of transplanted stem cells following TBI. Moreover, this study shows that twice daily, fractionated TBI does not improve the homing of donor BM cells to the recipient marrow. Homing of lineage negative, and of the subset of lineage negative, Kit positive donor BM cells, was actually significantly worse following the twice daily over 4 day TBI regimen.

Though the true hematopoietic stem and progenitor cells has yet to be fully defined, multiple studies do show that transplanted cells capable of reconstituting hematopoesis in lethally irradiated mice are lineage negative and Kit positive[25–28]. Cao et al. showed that such transplanted stem cells can be later recovered from the femurs[25]. Moreover, Cao et al showed that it takes weeks for substantial proliferation to occur. In an MR imaging study, Daldrup-Link et al. showed that the majority of stem cell homing to the marrow occurs within 4–24 hours following injection[29]. As in our study, Kimura et al. also used an 18 hour time point to test the homing of stem cells without any substantial proliferation[30].

This study was designed to accentuate any radiation dose or fractionation induced differences in the homing of lineage negative, Kit positive donor BM cells between groups.
by using a higher total dose in the single fraction arms (13.6 Gy versus 12 Gy) and by limiting lung dose to 3% (compared to 50% in the clinical setting) in the lung shielding groups.

Despite these attempts to accentuate differences which favored the fractionated arms, the fact that fractionated radiation therapy caused a decrease in donor hematopoietic cell homing compared to single dose radiation is a fresh observation for which we lack a definitive explanation. Kovacs et al. reported that fractionated radiation therapy generates two forms of dose-dependent damage in the marrow. In the first form of dose dependent damage, an early lesion arises in the blood-forming CAFC subpopulations. In the second form of dose dependent damage, a delayed lesion arises which involves the persistent expression of a dysfunctional microenvironmental phenotype\[31\]. Based on this data, we speculate that fractionated doses of irradiation may have produced more damage to host stromal environment than single dose irradiation thus, hampering the homing of infused donor hematopoietic stem and progenitor cells.

Of note, the dose rate of 2.35 Gy/minute used in this study was different from the clinical dose rate of 0.12 Gy/minute. However, Colis et al. showed that TBI dose rate, varying from 0.01 to 5.85 Gy/minute, did not impact homing of stem cells to the bone marrow\[10\].

Our data showing decreased hematopoietic stem and progenitor cell homing after TBI echo Collis et al. who showed an approximately five fold reduction in lineage negative hematopoietic cell homing to the BM compared to unirradiated control animals\[10\]. Similarly, comparing radiated to non-radiated mice, Plett et al found a 5 to 30 fold reduction in homing of stem cells capable of long-term hematopoiesis in secondary recipients\[11\].

Conversely, ours and the aforementioned data contravene the experience of Bastianutto et al. who found that local irradiation does induce a four fold greater homing of hematopoietic stem cells to the locally irradiated BM\[32\]. In this experiment, however, TBI was not performed in any group. Therefore, it remains possible that the effects of isolated local irradiation are quite different from TBI in the induction of hematopoietic stem cell homing.

Overall, multiple publications and our data support decreased hematopoietic stem and progenitor cell homing after TBI\[10, 11\]. However, this data must be interpreted with caution. Human data from our group and others suggests that the stem cell dose is not linearly related to survival. In fact, many series have shown that above an optimum stem cell dose (approximately $8-10 \times 10^6$ cells/kg) the probability of mortality actually increases with increasing stem cell dose\[33-35\]. Given this fact that (above an optimum level) increased stem cell dose actually decreases survival, one cannot simply assume that the decreased stem cell homing seen following TBI will necessarily diminish survival.

Multiple questions remain about the homing of lineage negative, Kit positive cells following TBI. Previous studies have shown that some fraction of transplanted stem cells do home to spleen\[36, 37\] \[38, 39\] and/or lung\[36, 39\]. Therefore, one may posit that TBI with or without lung shielding may increase homing to these other sites. However a prior iteration of these experiments, similar to those detailed here but with female mice (data not shown,) showed consistently less homing -- on a similar scale as shown for BM-- of GFP positive,
lineage negative, Kit positive cells to spleen, lung, and BM following TBI with or without lung shielding. Thus, it appears that TBI, with or without lung shielding, decreases homing of lineage negative, Kit positive cells to BM, spleen and lung.

Future Directions

Stem cell transplant is a complicated process with many effective approaches (eg. types chemotherapy used, done with or without TBI) and a multitude of variations (eg. dose of chemotherapy used, single fraction or multiple fraction TBI with or without lung dose reduction, low dose.) The absence of a definitively superior approach suggests that no optimum regimen will soon emerge. Therefore, each approach will need to optimized. Given the complexity of the successful transplant, we advocate making only those limited changes to the transplant regimen necessary to test the hypothesis while holding all other variables constant.

We have found no pre-clinical evidence that TBI with bilateral lung shielding improves stem cell homing. The mechanisms which explain the survival benefit seen in a subset of patients treated with lung dose reduced, twice daily TBI remain unknown[19]. However, given the success of lung dose reduction and absence of any homing advantage in preclinical models, we are pursuing lower doses of TBI in selected older patients.

Conclusion

The current data adds to the existing literature by showing that the survival benefit seen with lung dose reduced, twice daily TBI[19] likely does not arise from improved homing of hematopoietic stem and progenitor cell homing to the BM. However, no definite conclusion can be reached about homing of the true stem cell subset until that subset is adequately defined.

Figure 1. Mouse Total Body Irradiation and Lung Shielding
A Therapax DXT300 X-ray irradiator was used as the source of irradiation for all recipient mice used in the current study. Mice were anesthetized and place on a specifically designed table. The effective X-ray area can accommodate four mice each time. Mice were irradiated for the entire body without shielding (A), or with lead shielding to reduce lung exposure to 3% of the effective dose (B).
Figure 2. Flow Cytometric Analysis of Donor Bone Marrow Cells
All recipient mice were then injected with BM cells from B6-EGFP donors for which the vast majority of Lin− (98%) and Lin−Kit+ (99%) of donor BM cells were EGFP+.
Figure 3. Effect of Fraction Dose and Lung Shielding on Hematopoietic Cell Homing
Homing of EGFP donor Lin^-Kit+ cell to recipient BM was shown as percentages of total BM (top), Lin^- (middle) and Lin^-Kit+ (bottom) cell recovery in recipient BM were computed and presented as means with standard error bars respectively, showing that irradiation reduces hematopoietic cell homing to recipient BM and fractionated dose further reduces cell homing, with or without lung shielding. CON = No irradiation control. SD-NS = 13.6 Gray (Gy), single dose TBI without lung shielding. SD-BLS = 13.6 Gy single dose
TBI with bilateral lung shielding. BID-BLS = 12 Gy TBI in fractionated dose with bilateral lung shielding. BID-NS = 12 Gy TBI.
