Abstract

Code-switching is the practice of moving back and forth between two languages in spoken or written form of communication. In this paper, we address the problem of word-level language identification of code-switched sentences. Here, we primarily consider Hindi-English (Hinglish) code-switching, which is a popular phenomenon among urban Indian youth, though the approach is generic enough to be extended to other language pairs. Identifying word-level languages in code-switched texts is associated with two major challenges. Firstly, people often use non-standard English transliterated forms of Hindi words. Secondly, the transliterated Hindi words are often confused with English words having the same spelling. Most existing works tackle the problem of language identification using n-grams of characters. We propose some techniques to learn sequence of character(s) frequently substituted for character(s) in standard transliterated forms. We illustrate the superior performance of these techniques in identifying Hindi words corresponding to the given transliterated forms. Our test results show that the proposed model significantly increases the accuracy over existing approaches. We achieved F1-score of 98.0% for recognizing Hindi words and 94.8% for recognizing English words.

1 Introduction

Code-switching is a popular linguistic phenomenon where the speaker alternates between two or more languages even within the same sentence. In countries like India, where there are more than 20 widely used languages, code-switching is an even more pronounced feature, mostly among urban population (Thakur et al., 2007). Hindi and English are two popular ones among these languages, with millions of people communicating through them in pure forms or using a mixture of words from both the languages (code-switched), popularly known as ‘Hinglish’. Many multi-national brands use Hinglish taglines for promoting their products in India. For example, “Khushiyan ki home delivery”\(^1\) is the tag line for Domino’s Pizza \(^2\) India. Hinglish is also used for casual communication among friends, for example, “Main temple ke pass hoon” meaning “I am near the temple”. There are plenty of research works focusing on analyzing texts used in popular forums, like online social groups, for applications like opinion mining, sentiment analysis, etc. However, machine analysis of Hinglish or any other code-switched text poses the following challenges.

- **Inconsistent spelling usage**: Despite the availability of the standards for transliteration (e.g., ITRANS \(^2\)) of Devanagari script to Roman script (the Hindi language is based on Devanagari script while the English language is based on Roman script), people tend to use many inconsistent spellings for the same word. For example, the most common English transliteration for the Hindi word \(^3\) is 'mai', as observed from our data set. But people often use 'mein' or 'main' as alternatives.

- **Ambiguous word usage**: The transliterated word 'main', for the Hindi

word ही could be misinterpreted by a machine to be the English word.

In order to address the afore-mentioned challenges and to enable automated analysis for code-switched languages, we need to identify the language of individual words. In case of transliterated Hindi words, we also need to find the authentic script. For example, in the sentence ‘Main temple ke pass hoon’ the word ‘main’ is a non-standard transliterated form for the Hindi word मैं and ‘pass’ refers to the Hindi word पास and not the English word.

We propose some novel solutions to address the problem of word-level language identification in code-switched texts. Our major contributions can be summarized as below.

- We build a model to tackle the inconsistent spelling usage problem. The model learns the most common deviations from a standard transliteration scheme in English transliteration of Hindi words by identifying the erroneous character(s) that are frequently used in place of correct character(s) in standard transliterated forms.

- In addition to n-grams of characters, we use frequency of usage of a word in English and in Hindi languages as features for word-level language identification.

- We propose a technique using language and part-of-speech of neighboring words which, to the best of our knowledge, has not been applied before to solve this problem.

- We achieved F1-score of 98.0% for recognizing Hindi words and 94.8% for recognizing English words.

The rest of the paper is organized as follows. Section 2 describes the related work. Section 3 describes the data sets used. Section 4 describes the algorithms and features used. Section 5 describes the experiments conducted and their results.

2 Related Work

The socio-linguistic and grammatical aspects of code-switched texts have already been studied by many researchers. Ritchie and Bhatia (1996) and Kachru (1978) have discussed and examined different types of constraints on code-switching. Agnihotri (1998) discussed a number of examples of Hindi-English code-switching which do not comply with the constraints proposed in other literature. However, many of the constraints proposed for code switching, like the Free Morpheme Constraint (Sankoff and Poplack, 1981) and the Equivalence Constraint (Pfaff, 1979), are still widely applicable.

Automatic language identification research has focused on identifying both spoken languages as well as written texts. Language identification of speech has been studied by House and Neuburg (1977), where the authors assumed that the linguistic classes of a language are probabilistic functions of a Markov chain. Language identification of written texts has been studied at document-level as well as at word-level perspectives. Two major techniques adopted are n-gram (Cavnar and Trenkle, 1994) and dictionary-lookup (Řehůřek and Kolkus, 2009). Most of the existing research works on document-level language identification consider only mono-lingual documents (Hughes et al., 2006).

Word-level language identification in code-switched texts has received little attention so far. King and Abney (2013) have used weakly supervised methods based on n-grams of characters. However, their training data is limited to monolingual documents, which limits the capability to capture some patterns in code-switched texts. Nguyen and Dogruoz (2013) experimented with linear-chain CRFs to tackle the problem. But their contextual features are limited to bigrams of words. Our approach is more general in the sense we consider the language and POS (Part-of-speech) of the neighbouring words. So our approach will work for bigrams of words not present in training data.

Automatically identifying linguistic code-switching (LCS) points in code-switched texts have been studied by Joshi (1982), and Solorio and Liu (2008). Elfardy et al. (2013) tackled the problem of identifying LCS points at the word level in a given Arabic text. They used sound
change rules (SCR) that model possible phonological variant of the word, along with 3-gram model for dialect identification at word-level.

Aswani and Gaizauskas (2010) proposed a bi-directional mapping from character(s) in the Devanagari script to character(s) in the Roman script for the purpose of transliteration. But they have manually come up with a limited number of mappings. Dasigi and Diab (2011) used string based similarity metrics and contextual string similarity to identify orthographic variants in Dialectal Arabic.

3 Data Sets

In this section, we describe the datasets used for our experimentation.

3.1 Data set 1: Hinglish sentences

We have a dataset of 500 Hinglish sentences containing a total of 3,287 words (CNERG). Each word is labeled as Hindi (H) or English (E). Out of these, 2420 are labeled as Hindi words while the rest 867 are labeled as English words. Corresponding to each Hindi word, the authentic Devanagari script is also written. Some examples from this dataset are given below.

Bangalore\(E\) ke\(H=के\) technical\(E\) log\(H=लोग\)

We have another data set of 1000 sentences of social network chats. To avoid any bias, the data set was tagged manually by three people not associated with this work. The mean Cohen’s kappa coefficient of inter-annotator agreement between the sets of annotations was 0.852. There were few disagreements on the language of some named entities. An example from this dataset is given below.

Main\(H=मैं\) main\(E\) temple\(E\) ke\(H=के\) pass\(H=पास\) hoon\(H=हूँ\).

Above two data sets were clubbed to form the Data set 1.

3.2 Data set 2: Transliteration Pairs

The data set comprises of commonly used multiple transliterated forms of Hindi words. It contains 30,823 Hindi words (Roman script) followed by the corresponding word in Devanagari script (Gupta et al., 2012). Some examples from this dataset are given below.

3 http://cse.iitkgp.ac.in/resgrps/cnerg/
which \(w\) is an English word, for each word \(w\) in a Hinglish sentence. If we call this probability \(P(E, w)\), then \(P(H, w) = 1 - P(E, w)\), where \(P(H, w)\) is the probability with which \(w\) is a Hindi word.

### 4.1.1 Common Spelling Substitutions and String Similarity (Modified Edit Distance)

This feature is used to address the inconsistent spelling usage problem discussed in the Introduction section. To solve this problem, for every word we try to find the most similar word in our Transliterated Hindi Dictionary using string similarity algorithms, like ‘Edit Distance’ (Wagner and Fischer, 1974).

However, we observed cases in code-switching texts where this algorithm does not produce the intended outcome. For example, for the Hindi word खुशबू, the possible transliterated forms are khushboo and khushbu with the former being the standard one. With the Edit Distance algorithm applied over the two forms, we shall get a dissimilarity value of 2. The same algorithm applied over the strings khushbu and khushi (ख़ुशी), which refer to different Hindi words, also gives the same dissimilarity value. However, for all practical purposes, khushbu is much closer to khushboo than it is to khushi. It is an observed fact that people often tend to substitute, ‘u’ in place of ‘oo’ while writing transliterated forms. But the Edit Distance algorithm does not capture this fact. We call this type of substitutions as common spelling substitutions.

To overcome this problem, we have developed a ‘Modified Edit Distance’ (MED) algorithm (Fig. 2) which considers the common spelling substitutions. The idea is similar to Weighted Edit Distance (Kurtz, 1996), but in case of MED we automate the process of deciding the corresponding weights. We have experimented with four different methods to learn common spelling substitutions using the Transliteration Pairs data set. Here we present the working of the four methods.

#### Method 1

In this method, given the standard transliterated form \(w_1\) of a word and a non-standard form \(w_2\) of the same word, we try to generate substitution pairs by first aligning the consonants. We add ‘;’ at start and end of each word to act as delimiters. ‘;’

| Substitution Pair | Frequency |
|-------------------|-----------|
| ra;               | 1055      |
| na;               | 775       |

Table 1. Substitution pairs generated by Method 1

#### Method 2

For this method, the only difference with method 1 is in the way the segments are defined. We define a segment to be a sequence of characters delimited by two aligned consonants (delimiting consonants inclusive). The two words will contain same number of segments. We consider two corresponding segments as substitution pairs if they do not have identical sequence of letters.

```plaintext
e.g. \(w_1=;tera;\), \(w_2=;teraa;

; t e r a
\
; t e r a a

S1 = \{t, ter, ra;\}
S2 = \{t, ter, raa;\}
```

This generates a substitution pair (ra;, raa;).

Some substitution pairs generated by this method are given in Table 2.
| Substitution Pair | Frequency |
|-------------------|-----------|
| a                 | aa        | 7764      |
| a                 | ha        | 872       |

Table 2. Substitution pairs generated by Method 2

**Method 3**

In this method, we do not include any delimiter at the beginning and end of the words. Rest of the working is same as in method 2.

Some substitution pairs generated by this method are given in Table 3.

| Substitution Pair | Frequency |
|-------------------|-----------|
| a                 | aa        | 8674      |
| om                | on        | 1243      |

Table 3. Substitution pairs generated by Method 3

**Method 4**

In this method, we align the vowels also. Rest of the working is same as in Method 3.

For example, consider **main** (w1) and **mein** (w2) as two spelling variants of transliterated form of the Hindi word मैं. We first align ‘m’ of w1 with ‘m’ of w2, ‘i’ of w1 with ‘i’ of w2, and ‘n’ of w1 with ‘n’ of w2.

This generates the substitution pair (‘a’, ‘e’), i.e., ‘e’ has been used in place of ‘a’ interchangeably by the user. Some substitution pairs generated by this method are given in Table 4.

| Substitution Pair | Frequency |
|-------------------|-----------|
| i                 | ee        | 1742      |
| f                 | ph        | 1444      |

Table 4. Substitution pairs generated by Method 4

In all methods we keep some threshold *thresh* for the frequency of substitution pairs. Substitution pairs occurring less than *thresh* are not further considered. The comparison of performance of MED based on these four methods will be discussed in the section 5.7.

Let *subsList* be the list of substitution pairs. Each entry *s* in *subsList* has attributes *s_x*, *s_y*, and *s_f*, where (*s_x*, *s_y*) is the substitution pair and *s_f* is the corresponding frequency of occurrence.

Consider a substitution pair *s* which occurs with frequency *s_f* in the training data. Then the cost of using the substitution is *g*(*s_f*), i.e., a function of frequency *s_f*. Here, *g*(f) = k / (log10(f)), where, k is a constant.

\[
\text{modifiedEditDistance}(\text{transliteration } w_1, \text{transliteration } w_2, \text{list of substitutions } \text{subsList})
\]

\[
\begin{align*}
N &\leftarrow \text{length of } w_1 \\
M &\leftarrow \text{length of } w_2 \\
\text{initialize all elements of matrix } \text{dp}[N][M] \text{ with } 0 \text{ for } i \leftarrow 1 \text{ to } N: \\
&\text{for } j \leftarrow 1 \text{ to } M: \\
&\quad \text{if } w_1[i] = w_2[j]: \\
&\quad \quad v_1 \leftarrow \text{dp}[i-1][j-1] \\
&\quad \text{else:} \\
&\quad \quad v_1 \leftarrow \text{dp}[i-1][j-1] + 1 \text{/ substitution of a character} \\
&\quad \quad v_2 \leftarrow 1 + \text{dp}[i-1][j] \text{/ deletion of a character} \\
&\quad \quad v_3 \leftarrow 1 + \text{dp}[i][j-1] \text{/ insertion of a character} \\
&\quad \quad v_4 \leftarrow \infty \\
&\quad \text{for } s \text{ in } \text{subsList}: \\
&\quad \quad p \leftarrow \text{length of } s_x \\
&\quad \quad q \leftarrow \text{length of } s_y \\
&\quad \quad \text{if } w_1[i-p+1:i] = s_x \text{ and } w_2[j-q+1:j] = s_y: \\
&\quad \quad \quad v_4 \leftarrow \min( v_4, g(s) + \text{dp}[i-p][j-q] ) \\
&\quad \quad \quad \text{dp}[i][j] \leftarrow \min( v_1, v_2, v_3, v_4) \\
\text{output: } \text{MED}(w_1, w_2) = \text{dp}[N][M]
\end{align*}
\]

Fig 2. Pseudo code for Modified Edit Distance Algorithm

We have used logarithmic scaling as the frequencies of occurrences of the substitution pairs are very much skewed towards larger values. For every other insertion, deletion and substitution of a character, cost is 1 as is commonly used for Edit Distance. For each word *w* in test data, we try to match it against words in our **Transliterated Hindi Dictionary**. The word corresponding to the minimum cost and the minimum cost itself computed by the above algorithm are stored. The minimum cost so obtained for each word is **dissimilarityScore** for that word. The algorithm for MED is shown in Fig.2.

**4.1.2 Frequency of Occurrence in English and Hindi**

Here we address the ambiguous word usage problem discussed in the Introduction section. Consider that the test data contains the word...
`main`, which can correspond to the Hindi word `मैं` or the English word. If we decide its language randomly, then the expected accuracy of identifying the correct language is 50%. If we know that `main` in English language is having higher usage frequency than the word `मैं` in Hindi language, then the probability of the test data word `main` being an English word increases.

Using formula (1), we compute the value corresponding to this feature and we call it English score (`eng_score`). First, we use logarithmic scaling on frequencies of occurrences of English words to do away with its skewness towards large values. Then, we normalize the word frequency values with respect to the largest frequency observed.

\[
M = \max ( \log(\text{freq}(q)) )
\]

\[
\forall \text{ word } q \in \text{Hindi Dictionary}
\]

For a given word `w` in the test data,

\[
\text{score}(w) = \frac{\log(\text{freq}(w))}{M}
\]

\[
\text{eng\_score}(w) = 0, \text{ if } w \text{ not in English Dictionary}
\]

\[
= \text{score}(w), \text{ otherwise } ...(1)
\]

Similarly, we calculate the Hindi score (`hin_score`) using formula (2). However, first the MED algorithm is used to identify the closest matching Hindi word `hw` for a given word in the test data.

\[
M = \max ( \log(\text{freq}(q)) )
\]

\[
\forall \text{ word } q \in \text{Hindi Dictionary}
\]

For a given word `w` in the test data,

\[
\text{score}(w) = \frac{\log(\text{freq}(hw))}{M}
\]

\[
\text{hin\_score}(hw) = \text{score}(w)
\]

\[
... (2)
\]

Thus, we get English score and Hindi score for each word in the Dataset 1. The density distributions of `eng\_score` and `hin\_score` are shown in Fig. 3(a) and Fig. 3(b) respectively.

### 4.1.3 Character N-grams

This follows the idea that, in Hinglish sentences some contiguous sequences of letters occur more frequently in words of one language as compared to the words of the other language. For example, bigram `es` frequently occurs at the end of English words (like, roses, fries), often denoting plural morphological forms. We considered bigrams and trigrams of characters for the task of word-level language identification. We used the technique of Delta TF-IDF, which has been shown to be more effective in binary classification of class imbalanced data using unigrams, bigrams, and trigrams (Martineau et al., 2009)

For any term `t` (n-gram of characters) in word `w`, the Delta TF-IDF score `V` is computed using formula (3).

\[
V(t,w) = n(t,w) \times \log_2 \left( \frac{H_t}{E_t} \right)
\]

\[
... (3)
\]

Where `n(t,w)` is the frequency count of term `t` in word `w`. `H_t` and `E_t` are the number of occurrences of term `t` in the English and Hindi dictionaries. Thus for every word `w`, we generate a set of feature values, with each n-gram `t` contributing one value.

### 4.2 Using Context Level Features: Classifier 2

All the previous features we have discussed focus on individual words of a code-switched sentence on a stand-alone basis, i.e., independent of the surrounding words or context. However, language usage of words in code-switched sentences may follow certain patterns, like words of a language are often surrounded by words of the same language (King and Abney, 2013). We tried to capture this context-dependence by considering the language and the POS of the surrounding words. For example, words on the two sides of conjunctions `and`, `aur` (`और`), etc. are usually of same language as the conjunction.

Our Classifier 2 operates over POS-tagged Hinglish sentences and the output from Classifier 1, i.e., P(E, w) (Refer to Fig.1.). The notations and symbols are shown in table 5, and the corresponding procedure is presented in Fig.4.

We annotated POS of each word in the training data set with POS taggers. For English, we used Stanford NLP Maxent POS tagger (Toutanova et al., 2003). In case, the word has more than one
possible POS usage, we consider the most frequent POS usage. For Hindi words, we used POS tagger by Reddy and Sharoff (2011). For each word \( w \) in the training data, we assign an identifier (\( \text{id} \)) to it, where \( X \) can take values ‘E’ (for English) or ‘H’ (for Hindi), and \( P \) is the corresponding POS of the word. For example, if ‘car’ is an English noun (NN), then its id will be as E\_NN.

We then count the number of occurrences of various bigrams of ids’ in the training data. We use these counts to calculate the conditional probability of an identifier to occur given the previous identifier e.g. \( P(\text{id}_2|\text{id}_1) \) is the probability that identifier \( \text{id}_1 \) will be followed by identifier \( \text{id}_2 \).

For each word \( w \), we have at most two possible candidate interpretations - Hindi word \( w_H \) with POS as \( PwH \), and English word \( w_E \) with POS as \( PwE \). \( w_H \) is found using MED algorithm and \( w_E \) is found using English Dictionary lookup. Now \( w \) refers to \( w_E \) with probability \( P(E, w) \), and refers to \( w_H \) with probability \( P(H, w) \) e.g. if \( w \) is ‘main’, then \( w_H \) is \( \# \) and \( w_E \) is the English word main. Now the identifier corresponding to \( w_H \) will be H\_PRP as \( \# \) is a Hindi personal pronoun.

For a sentence \( S \) with \( N \) words, we can have a maximum of \( 2^N \) such possibilities. Now calculating the maximum score over these possibilities has optimal sub-structures, which lets us use dynamic programming. Algorithm for Classifier 2 is presented in Fig.4. We built a similar model using trigrams of identifiers.

For the first three words of the sentence ‘Main main temple ke pass hoon’:

- **Case 1**: Main (H\_PRP) main (E\_JJ) temple (E\_NN)
- **Case 2**: Main (E\_JJ) main (E\_JJ) temple (E\_NN)
- **Case 3**: Main (H\_PRP) main (H\_PRP) temple (E\_NN)
- **Case 4**: Main (E\_JJ) main (H\_PRP) temple (E\_NN)

Case 1 is the correct case. The bigrams of identifiers corresponding to the case 1 i.e. H\_PRP-E\_JJ and E\_JJ-E\_NN occur much more frequently in the training data as compared to bigrams of other cases.

### Table 5. Notations and Symbols for classifier 2

| Symbol                  | Meaning                                                                 |
|-------------------------|-------------------------------------------------------------------------|
| Sentence S              | A Hinglish sentence which is a sequence of words \( w_1\ w_2\ w_3\ \ldots \ w_N \) |
| Matrix prob_pos[M][M]   | Current probability of the current word’s identifier (id) being i, given that the identifier (id) of the previous word is j, as learnt from the training data. |
| Array eng_prob[N]       | Probability of the \( i \)th word in sentence to be English, as provided by Classifier 1. |
| Array hin_tag[N]        | POS tag of \( w_H \) |
| Array eng_tag[N]        | POS tag of \( w_E \) |
| Integer M              | Total number of identifiers possible |

### Algorithm for Classifier 2 (using identifier bigram)

Consider following cases for the first three words of the sentence ‘Main main temple ke pass hoon’:

- **Case 1**: Main (H\_PRP) main (E\_JJ) temple (E\_NN)
- **Case 2**: Main (E\_JJ) main (E\_JJ) temple (E\_NN)
- **Case 3**: Main (H\_PRP) main (H\_PRP) temple (E\_NN)
- **Case 4**: Main (E\_JJ) main (H\_PRP) temple (E\_NN)

Fig. 4. Algorithm for Classifier 2 (using identifier bigram)

### 5 Experimentation and Results

In this section, we shall discuss the experiments we carried out and the results obtained. We have used 10-fold cross validation technique. We experimented with different classifiers like Decision Tree, SVM and Random Forest, provided by Scikit Learn (Pedregosa et al., 2011).
5.1 Experiment 1: Presence in English Dictionary

In this experiment a word is classified as belonging to English class if it is present in English Dictionary otherwise the word is classified as belonging to Hindi class.

For this experiment, we sorted the words of the English Dictionary in decreasing order of the frequency of occurrences of words. Then we considered only the top K words for the experiment. The results for different values of K are shown in Table 6.

| K   | HPR  | HRE  | HF1  | EPR  | ERE  | EF1  |
|-----|------|------|------|------|------|------|
| 100 | 0.74 | 0.98 | 0.84 | 0.31 | 0.02 | 0.04 |
| 500 | 0.76 | 0.96 | 0.85 | 0.59 | 0.15 | 0.24 |
| 1000| 0.79 | 0.95 | 0.86 | 0.69 | 0.28 | 0.40 |
| 5000| 0.85 | 0.93 | 0.89 | 0.75 | 0.55 | 0.64 |
| 10000| 0.87 | 0.86 | 0.87 | 0.63 | 0.64 | 0.63 |
| ALL | 0.92 | 0.39 | 0.55 | 0.35 | 0.91 | 0.50 |

Table 6. Results of Experiment 1

We observed that with an increase in the number of words in the English dictionary, more English words will be correctly identified as ‘English’ words, resulting in increased recall values for the ‘English’ class (ERE). But at the same time more Hindi words would be incorrectly marked as English, resulting in decrease in HRE.

5.2 Experiment 2: King-Abney’s approach

In this experiment we run the King’s (2013) n-grams and context level algorithms on our data set. The results are shown in Table 7.

|     | HPR  | HRE  | HF1  | EPR  | ERE  | EF1  |
|-----|------|------|------|------|------|------|
| Naive Bayes | 0.66 | 0.83 | 0.74 | 0.39 | 0.20 | 0.27 |
| HMM  | 0.75 | 0.91 | 0.83 | 0.59 | 0.29 | 0.39 |
| CRF  | 0.76 | 0.96 | 0.85 | 0.76 | 0.28 | 0.41 |

Table 7. Results of Experiment 2

5.3 Experiment 3: Using Delta TF-IDF on n-grams of characters (Our Approach)

In this experiment we used only one of our features for classification. We have used Delta TF-IDF scores of n-grams of characters as features in our Classifier 1. The results of experiment 3 are presented in Table 8. The best results are obtained using Random Forest with number of trees equal to 10.

|     | HPR  | HRE  | HF1  | EPR  | ERE  | EF1  |
|-----|------|------|------|------|------|------|
| Random Forest | 0.89 | 0.79 | 0.84 | 0.52 | 0.71 | 0.6  |

Table 8. Results of Experiment 3

5.4 Experiment 4: All word-level features (Classifier 1)

In this experiment we show the results produced by our Classifier 1 i.e., only using word-level features. Results of this experiment are presented in Table 9. We can see using other features, F1 scores have significantly increased.

|     | HPR  | HRE  | HF1  | EPR  | ERE  | EF1  |
|-----|------|------|------|------|------|------|
| Random Forest | 0.95 | 0.98 | 0.97 | 0.94 | 0.85 | 0.89 |

Table 9. Results of Experiment 4

5.5 Experiment 6: Classifier 2

As input to Classifier 2, we used POS tagged Hinglish sentences and the output of Classifier 1, Fig 5. ROC curve for Random Forest Classifier based on all word-level features.

Thus best results came corresponding to Random Forest classifier, with number of trees = 10, and based on following word-level features:

- Delta TF-IDF on n-grams of characters
- eng_score

- dissimilarityScore

The corresponding ROC curve has been shown in Fig 5. The AUC (Area Under the curve) is 0.98.
corresponding to the output from Experiment 4. We performed two experiments with Classifier 2 using bi-grams and tri-grams of identifiers. The results are shown in Table 10.

| Identifier     | HPR | HRE | HFI | EPR | ERE | EF1 |
|----------------|-----|-----|-----|-----|-----|-----|
| bi-grams       | 0.974 | 0.969 | 0.972 | 0.920 | 0.934 | 0.926 |
| tri-grams      | 0.983 | 0.977 | 0.980 | 0.941 | 0.955 | 0.948 |

Table 10. Results of Experiment 6

The accuracy of Classifier 2 obtained on using identifier tri-grams is more than the accuracy obtained on using identifier bi-grams. This is probably because usage of trigrams captures the context more efficiently. Moreover the improvement offered by Classifier 2 over Classifier 1 is only little. This is mainly because of the already high accuracy values of Classifier 1.

We found that the percentage of named entities in the Dataset 1 is 8.59%. We observed that the percentage of named entities in the wrongly classified words is 23.2%.

5.6 Experiment 7: Comparing four methods of creating substitution pairs

In this experiment we compare the results of previously described four methods to create substitution pairs. The results of this experiment is shown in Fig. 6. The K value which was defined in section 4.1.1 is varied to compare the results. It is observed that Method 2 gives best results among all methods discussed.

6 Conclusion

In this paper, we addressed the problem of word-level language identification in bilingual code-switched texts. We proposed a novel idea of utilizing the patterns in Hinglish sentences by considering the language and the POS of consecutive words. We proposed four different techniques to identify common spelling substitutions. Our error analysis shows that a significant fraction of the errors made by the classifiers are actually named entities which are names of people or places, and can be considered either as Hindi or as English. In future, we would like to explore the changes of code-switching behavior from person to person. Also, we shall focus on other pairs of languages, like English-Bengali, English-Gujarati, etc. and also on word-level identification in multilingual code switched texts (i.e. having more than two languages).
