J/ψ suppression at $\sqrt{s} = 200$ GeV
in the comovers interaction model

Abstract

The yield of $J/\psi$ per binary nucleon-nucleon collision in $AuAu$ and $CuCu$ collisions at $\sqrt{s} = 200$ GeV is computed in the framework of the dual parton model, supplemented with final state interaction (comovers interaction). For the latter we use the same value of the cross-section, $\sigma_{co} = 0.65$ mb, which describes the anomalous $J/\psi$ suppression observed at CERN-SPS energies. Several possibilities for the value of the absorptive cross-section are considered. Shadowing is introduced in both the comovers and the $J/\psi$ yields. A comparison with the results at CERN-SPS, including a prediction for $InIn$ collisions, is also presented.
I. INTRODUCTION

\( J/\psi \) production in proton-nucleus collisions is suppressed with respect to the characteristic \( A^1 \) scaling of lepton pair production (Drell-Yan pairs). This suppression is generally interpreted as a result of the multiple scattering of a pre-resonance \( c - \bar{c} \) with the nucleons of the nucleus (nuclear absorption). In these interactions, the \( c - \bar{c} \) pair can transform into another \( c - \bar{c} \) pair with vanishing projection into \( J/\psi \). The corresponding cross-section \( \sigma_{abs} \) is called absorptive cross-section. This interaction is generally described in the framework of a probabilistic Glauber model. However, at high energies, the coherence length increases and the projectile interacts with the nucleus as a whole. As a consequence the probabilistic Glauber formula breaks down [1] [2] and, thus, the extrapolation from CERN-SPS energies to RHIC ones (\( \sqrt{s} = 200 \) GeV) is not straightforward.

The NA50 collaboration has observed [3] the existence of anomalous \( J/\psi \) suppression in \( \textit{Pb} - \textit{Pb} \) collisions, i.e. the \( J/\psi \) suppression in central \( \textit{Pb} - \textit{Pb} \) collisions clearly exceeds the one expected from nuclear absorption. Such a phenomenon was actually predicted by Matsui and Satz [4] as a consequence of deconfinement in a dense medium. It can also be described as a result of final state interaction of the \( c - \bar{c} \) pair with the dense medium produced in the collision (comovers interaction). The final results [3] of the NA50 collaboration can be described using an effective cross-section \( \sigma_{co} = 0.65 \) mb [5]. Since this is a low energy cross-section it is not expected to change significantly in going from CERN-SPS to RHIC energies. Therefore the prediction of the \( J/\psi \) suppression due to comovers interaction at RHIC seems to be quite safe. However, at these energies it is necessary to introduce shadowing corrections. These are small at CERN-SPS energies. Moreover, they cancel to a large extend in the ratio of \( J/\psi \) over Drell-Yan pair production measured by NA50. At RHIC energies, however, the Drell-Yan pair production is not measured and the \( J/\psi \) suppression is presented as a ratio of the \( J/\psi \) yield over the average number of binary nucleon-nucleon collisions – where the effect of shadowing is clearly present.

II. THE MODEL

The ratio \( R_{AB}^{J/\psi} (b) \) of the \( J/\psi \) yield over the average number of binary nucleon-nucleon collisions, \( n(b) \), in \( AB \) collisions is given by
\begin{equation}
R_{AB}^{J/\psi} (b) = \frac{dN_{J/\psi}^{AB} (b)/dy}{n(b)} = \frac{dN_{J/\psi}^{AB}/dy}{\int d^2s \sigma_{AB} (b) n(b, s) S_{abs}^{(b, s)} S_{co}^{(b, s)}} . \tag{1}
\end{equation}

Here \( \sigma_{AB} (b) = 1 - \exp[-\sigma_{pp} AB T_{AB} (b)] \) where \( T_{AB} (b) = \int d^2s T_A (s) T_B (b-s) \) and \( T_A (b) \) is the profile function obtained from Wood-Saxon nuclear densities [6], and

\[ n(b, s) = AB \sigma_{pp} T_A (s) T_B (b-s)/\sigma_{AB} (b) . \tag{2} \]

Upon integration of (2) over \( d^2s \) we obtain the average number \( n(b) \) of binary nucleon-nucleon collisions at fixed impact parameter \( b \).

The factors \( S_{abs} \) and \( S_{co} \) in (1) are the \( J/\psi \) survival probability due to nuclear absorption and comovers interaction, respectively.

In writing eq. (1) we have assumed that the \( J/\psi \) yield in the absence of final state interaction (i.e. \( S_{abs} = S_{co} = 1 \)) scales with the number of binary nucleon-nucleon collisions. In this case \( R_{AB}^{J/\psi} \) coincides with the \( J/\psi \) yield in \( pp \) collisions.

\section{Comovers interaction.}

The survival probability \( S_{co} (b, s) \) of the \( J/\psi \) due to comovers interaction is obtained by solving the gain and loss differential equations which govern the final state interactions with the co-moving medium [7]

\[ \tau \frac{dN_{J/\psi} (b, s, y)}{d\tau} = -\sigma_{co} N_{J/\psi} (b, s, y) N_{co} (b, s, y) \tag{3} \]

where \( N_{J/\psi} \) and \( N_{co} \) are the densities (i.e. number per unit of transverse surface) of \( J/\psi \) and comovers (charged + neutral), respectively. In eq. (3) we have neglected a gain term resulting from the recombination of \( c \) and \( \bar{c} \) into \( J/\psi \). This is natural in our approach since the cross-sections for recombination (gain) is expected to be substantially smaller than \( \sigma_{co} \). The possibility of such a recombination, giving sizable effects at RHIC energies, has been considered by several authors [8]. It will be most interesting to see whether the data confirm or reject such an effect.

In writing eq. (3) we have neglected transverse expansion and assumed a dilution in time of the densities due to longitudinal motion which leads to a \( \tau^{-1} \) dependence on proper time \( \tau \). Eq. (3) can be solved analytically. The solution is invariant under the change \( \tau \rightarrow c \tau \). Thus, the result depends only on the ratio \( \tau_f/\tau_0 \) of final over initial time. Using the inverse proportionality between proper time and densities, we put \( \tau_f/\tau_0 = N_{co} (b, s, y)/N_{pp} (y) \), i.e. we assume that the interaction stops when the densities have diluted, reaching the value of the \( pp \) density at the same energy. At \( \sqrt{s} = 200 \text{ GeV} \)
and \( y^* \sim 0 \), 
\[ N_{pp}(0) = \frac{3}{2} \left( \frac{dN^{ch}/dy}{dy} \right)_{y^*=0}/\pi R_p^2 \sim 2.24 \text{ fm}^{-2}. \]
Note the increase in the \( pp \) density form 1.15 fm\(^{-2}\) at CERN-SPS to 2.24 fm\(^{-2}\). Since the corresponding increase in the \( AuAu \) densities is approximately the same, the average value of \( \tau_f/\tau_0 \) is about the same at the two energies (of the order of \( 5 \div 7 \)).

The solution of eq. (3) is given by [5]
\[
S^{co}(b, s) \equiv \frac{N^{J/\psi(f\text{inal})}(b, s, y)}{N^{J/\psi(\text{initial})}(b, s, y)} = \exp \left[ -\sigma_{co} N^{co}(b, s, y) \ln \left( \frac{N^{co}(b, s, y)}{N_{pp}(0)} \right) \right]. \tag{4}
\]

b) **Comovers density in the dual parton model.** The main ingredient in order to compute the survival probability \( S^{co} \) is the comovers density \( N^{co} \). Note that \( N^{co} \) is the comovers density at initial time \( \tau_0 \), i.e. the density produced in the primary collision. It can be computed in the dual parton model [9]. It can be seen from eq. (6.1) of ref. [9] that this density is given by a linear combination of the average number of participants and of binary nucleon-nucleon collisions, and for \( A = B \) can be written as
\[
N^{co}_{NS}(b, s, y) = \frac{3}{2} \frac{dN^{ch}_{NS}(b, s, y)}{dy} = \frac{3}{2} [C_1(b) n_A(b, s) + C_2(b) n(b, s)] \tag{5}
\]
where
\[
n_A(b, s) = A T_A(s) \left[ 1 - \exp \left( -\sigma_{pp} B T_B(b - s) \right) \right]/\sigma_{AB}(b) \tag{6}
\]
and \( n(b, s) \) is given by eq. (2). The factor \( 3/2 \) takes care of the neutrals. The coefficients \( C_1(b) \) and \( C_2(b) \) are obtained from string multiplicities which are computed in DPM as a convolution of momentum distributions functions and fragmentation functions. These functions are universal, i.e. the same for all hadronic and nuclear processes. Thus, we use the same expressions as at CERN energies. For details see [10]. The numerical values of \( C_1(b) \) and \( C_2(b) \) in \( AuAu \) and \( CuCu \) collisions at \( \sqrt{s} = 200 \) computed in the rapidity interval \( |y^*| < 0.35 \) for various values of \( b \) and per unit rapidity are given in Table 1. We also give in this table the corresponding values for \( PbPb \) and \( InIn \) at \( p_{\text{lab}} = 158 \text{ GeV/c} \).

We see from Table 1 that \( C_2 \) is significantly larger than \( C_1 \) at RHIC energies. Thus, DPM leads to multiplicities which have a behaviour closer to a scaling with the number of binary collisions rather than to a scaling with the number of participants. Actually, with increasing energies the ratio \( C_2/C_1 \) increases and one obtains a scaling in the number of binary collisions. This is a general property of Gribov’s Reggeon Field Theory which is known
as AGK cancellation [11] – analogous to the factorization theorem in perturbative QCD and valid for soft collisions in the absence of triple Pomeron diagrams. It is well known that this behaviour is inconsistent with data which show a much smaller increase with centrality. As discussed in detail in [10] such a discrepancy is due to shadowing which is important at RHIC energies and has not been taken into account in eq. (5). This is precisely the meaning of label NS (no shadowing) in this equation.

c) Shadowing. Following ref. [10,12,13] shadowing corrections are computed, without free parameters, in terms of the measured value of the diffractive cross-section. Indeed, in the framework of Gribov’s Reggeon Field Theory, the same triple Pomeron diagrams which describe high mass diffraction are responsible for the shadowing corrections. While the contribution of the triple Pomeron diagram to high mass diffraction is positive, its contribution to the total cross-section is negative, due to the presence of s-channel discontinuities which correspond to interference terms. Thus, the triple Pomeron diagrams (with triple Pomeron coupling determined from high-mass diffraction data) produce a decrease of the charged yield as given by eqs. (5)-(7), thereby violating the AGK cancellation. In AB collisions this reduction is given\[ by [10,12]

\[ S_{ch}^{h}(b, s, y) = \frac{1}{1 + A \frac{F_{h}(y)}{T_{A}(s)}} \frac{1}{1 + B \frac{F_{h}(y)}{T_{B}(b - s)}}. \] (7)

Here the function $F(y)$ is given by the integral of the ratio of the triple Pomeron cross-section $d^{2}\sigma_{PPP}/dYdt$ at $t = 0$ over the single Pomeron exchange cross-section $\sigma_{P}$:

\[ F_{h}(y) = 4\pi \int_{Y_{\text{min}}}^{Y_{\text{max}}} dY \frac{1}{\sigma_{P}} \frac{d^{2}\sigma_{PPP}}{dYdt} \bigg|_{t=0} = C \exp(\Delta Y_{\text{max}}) - \exp(\Delta Y_{\text{min}}) \] (8)

where $Y_{\text{min}} = \ell n(R_{A}m_{N}/\sqrt{3})$, $\Delta = 0.13$ and $C = 0.31 \text{ fm}^{2}$. The value of $Y_{\text{max}}$ depends on the rapidity of the produced particle. For $y^{*} = 0$ we have $Y_{\text{max}} = 1/2\ell n(s/m_{T}^{2})$ where $m_{T}$ is the transverse mass of the produced particle. For charged particles we use $m_{T} = 0.4 \text{ GeV}$ and for a $J/\psi$ $m_{T} = 3.1 \text{ GeV}$.

\[ A \text{ more sophisticated calculation using other triple Regge diagrams, with parameters constrained from HERA data can be found in ref. [13]. The results, however, are very similar to the ones obtained from eqs. (7)-(8).} \]
It has been shown in [10] that with the shadowing resulting from eqs. (7)-(8) a good description of the centrality dependence of charged multiplicities at mid-rapidities is obtained at RHIC energies ($\sqrt{s} = 130$ and 200 GeV). More precisely one has

$$N^{co}(b, s, y) = N^{co}_{NS}(b, s, y) S^{ch}_{sh}(b, s, y)$$

(9)

where the two factors in the r.h.s. are given by eqs. (5) and (7), respectively.

With this expression of the density of comovers we can compute the $J/\psi$ survival probability $S^{co}$, eq. (4). The $J/\psi$ suppression $R_{AB}^{J/\psi}$ is given by eq. (1) with the following replacement in its numerator

$$n(b, s) \rightarrow n(b, s) S_{sh}^{J/\psi}(b, s, y).$$

(10)

Indeed, as discussed above, in writing the numerator of eq. (1) we have assumed that the $J/\psi$ yield in the absence of final state interaction ($S^{abs} = S^{co} = 0$) scales with the number of binary collisions. This is only true when shadowing is neglected. The effects of shadowing on the $J/\psi$ yield are introduced with the replacement (10) in the numerator of eq. (1).

d) **Nuclear absorption.** The formula for nuclear absorption used in the literature is obtained in a probabilistic Glauber model. One has

$$S^{abs}(b, s) = \frac{[1 - \exp(-A T_A(s) \sigma_{abs})][1 - \exp(-B T_B(b-s)\sigma_{abs})]}{\sigma_{abs}^2 AB T_A(s) T_B(b-s)}.$$ 

(11)

As discussed in the Introduction, this formula breaks down at high-energy due to the increase of the coherence length [1] [2]. In the limit of $s \rightarrow \infty$, the relevant equation is quite simple. The change consists in the replacement

$$\frac{1}{\sigma_{abs}} [1 - \exp(-\sigma_{abs} A T_A(b))] \Rightarrow A T_A(b) \exp \left[ -\frac{1}{2} \sigma_{c\pi-N} A T_A(b) \right]$$

(12)

in each of the two factors in the numerator of (11). The corresponding formula at finite energies which interpolates between (1) and (2) has also been derived [1]. The change in going from (11) to (12) is twofold. There is a change in the form of the expression and, moreover, $\sigma_{abs}$ has been replaced by the total $c\pi-N$ cross-section $\sigma_{c\pi-N}$. If $\sigma_{c\pi-N} \sim \sigma_{abs}$ the change from low energies to asymptotic ones is small. Indeed the two expressions coincide at the first and second order in the development of the exponential, and since $\sigma_{abs}$ is small, the low energy result will not be significantly changed. However, if $\sigma_{c\pi-N}$ is significantly larger than its absorptive part, $\sigma_{abs}$, the $J/\psi$ suppression due to final state interaction...
within the nucleus will be larger at high energies. The latter possibility seems to be ruled out by preliminary data [14] on $dAu$ collisions which show a rather small suppression at mid-rapidities.

In the next section we present the calculation of $J/\psi$ suppression in $AuAu$ and $CuCu$ collisions using eq. (11) with the value $\sigma_{abs} = 4.5$ obtained from the $pA$ data at CERN-SPS. With these values of $\sigma_{abs}$ the results obtained with eqs. (1) and (2) are practically the same. We also present the results obtained with smaller values of $\sigma_{abs}$ ($\sigma_{abs} = 0$, 1 mb and 3 mb).

### III. NUMERICAL RESULTS

We compute first the inclusive charged particle multiplicity given by

$$\frac{dN^{ch}}{dy}(b, y) = \int d^2 s \frac{dN^{ch}}{dy}(b, s, y) S^{ch}_{sh}(b, s, y).$$ \hspace{1cm} (13)

At mid-rapidities, this quantity can be computed at various centralities using the coefficients $C_1(b)$ and $C_2(b)$ in Table 1 and eq. (7). The calculations for $AuAu$ collisions at mid-rapidities are shown in Fig. 1 and compared with experiment [15]. As predicted in [10] a reasonable description of the data is obtained. An increase by a factor 1.13 between $\sqrt{s} = 130$ GeV and $\sqrt{s} = 200$ GeV for central collision was also predicted in [10] – in agreement with present data.

In Fig. 2 we compare the result of our calculations of $R_{J/\psi}^{AB}(b)$ in eq. (1) for different systems: $PbPb$ and $InIn$ at CERN-SPS ($p_{lab} = 158$ GeV/c) and $AuAu$ and $CuCu$ at $\sqrt{s} = 200$ GeV. In all cases the normalization is arbitrary but the same for all. It corresponds to taking $dN_{pp}^{J/\psi}/dy = 1$ in eq. (1). Also in all cases we use $\sigma_{co} = 0.65$ mb and $\sigma_{abs} = 4.5$ mb. An important feature of our results is that, at a given energy, the results for the lighter systems are rather close to the ones for the heavier ones, at the same values of $N_{part}$. We

\footnote{The results for $PbPb$ are identical to those in the first paper of [5], except that in [5] the ratio $J/\psi$ over $DY$ was plotted versus $E_T$ (the energy deposited in the NA50 calorimeter). Moreover, for large $E_T$ (beyond the “knee” of the $E_T$ distribution) the effect of the fluctuation in the comovers multiplicity was included. This is not the case in Fig. 2 since, in a plot versus $N_{part}$, such a situation does not arise.}
also see that the $J/\psi$ suppression is much larger at RHIC energies and reaches a factor 10 for central $AuAu$ collisions.

In Fig. 3 we present again the result of our calculation of $R_{AuAu}^{J/\psi}(b)$ in eq. (1), with the normalization given by the measured value of $dN_{pp}^{J/\psi}/dy$ at $\sqrt{s} = 200$ GeV [16]. All curves are obtained with $\sigma_{co} = 0.65$ mb and different values of $\sigma_{abs}$ ($\sigma_{abs} = 0$, 1mb, 3 mb and 4.5 mb). The suppression for central collisions varies between a factor of 6 for $\sigma_{abs} = 0$ and a factor of 10 for $\sigma_{abs} = 4.5$ mb. Even in the former case the suppression is twice as large as the one obtained in a QCD based nuclear absorption model [17].

The results in Fig. 2 for $PbPb$ and $InIn$ has been obtained without including shadowing. Using eq. (7) it turns out that, at CERN-SPS, the shadowing on the $J/\psi$ is negligibly small. However, for the comovers ($m_T = 0.4$ GeV), its effect is of the order of 15 %. Here the values of $Y_{max}$ and $Y_{min}$ in eq. (8) are quite close to each other and our equations (and in particular the expression of $Y_{min}$) are not accurate enough for a reliable calculation. If, however, an effect of shadowing of the order of 15 % is present, the values of $C_1$ and $C_2$ in Table 1 should be increased by the same amount in order to restore agreement [10] with the experimental values of the charged multiplicities in $PbPb$ at $p_{lab} = 158$ GeV/c. This, in turn, would result in a larger $J/\psi$ suppression at RHIC. The maximal effect occurs in the case $\sigma_{abs} = 0$ and is of the order of 20 % for central $AuAu$ collisions.

**IV. CONCLUSIONS**

In a comovers interaction framework we have computed the yield of $J/\psi$ per binary nucleon nucleon collision versus the number of participants in $PbPb$ and $InIn$ collisions at CERN-SPS ($p_{lab} = 158$ GeV/c) and in $AuAu$ and $CuCu$ at $\sqrt{s} = 200$ GeV. At RHIC energies shadowing corrections to both the $J/\psi$ and the comovers multiplicities are very important and have been included in the calculations. We have found that, at a given energy, the $J/\psi$ suppression for the lighter and heavier systems are similar, at the same value of $N_{part}$. We have also found that the $J/\psi$ suppression at RHIC is significantly larger than at SPS. For central $AuAu$ collisions it reaches a factor of 10 for $\sigma_{abs} = 4.5$ mb and a factor 6 for $\sigma_{abs} = 0$. The value of $\sigma_{abs}$ has to be determined from the $dAu$ data. Preliminary results [16] favor a rather small value, $\sigma_{ab} \approx 1$ mb.

We have argued that these values could be underestimated by about 20 %. Experimental values of the $J/\psi$ suppression significantly smaller that the one in Fig. 3 would not be
consistent with the comovers interaction model, at least in its present formulation.

Finally, an important difference between the $J/\psi$ suppression pattern in a comovers interaction model and in a deconfining scenario is that, in the former case, the anomalous suppression sets in smoothly from peripheral to central collisions – rather than in a sudden way when the deconfining threshold is reached. The NA50 results have not allowed to disentangle these two possibilities. However, at RHIC energies, the relative contribution of the comovers is strongly enhanced in our approach, and a clear cut answer to this important issue should be obtained.

FIG. 1. Multiplicity of charged particles per participant pairs, versus $N_{\text{part}}$, computed from (13) are compared to experimental data from PHENIX [15].
FIG. 2. $R_{AB}^{J/\psi}(b)$ for AuAu collisions at $\sqrt{s} = 200$ GeV (full curve), CuCu collisions at $\sqrt{s} = 200$ GeV (dashed curve), PbPb at $p_{lab} = 158$ GeV/c (dotted curve) and InIn at $p_{lab} = 158$ GeV/c (dashed-dotted curve). All the results have been obtained with $\sigma_{co} = 0.65$ mb and $\sigma_{abs} = 4.5$ mb. The normalization, the same for all four curves, is arbitrary. It corresponds to taking $dN_{pp}^{J/\psi}/dy = 1$ in eq. (1).
FIG. 3. $R_{\text{pA}}^{J/\psi}(b)$ for $AuAu$ collisions at $\sqrt{s} = 200$ GeV multiplied by the dilepton branching ratio, normalized to the measured value in $pp$ collisions [16]. From up to down: result with $\sigma_{\text{co}} = 0.65$ mb and $\sigma_{\text{abs}} = 0$ mb (dashed curve), result with $\sigma_{\text{co}} = 0.65$ mb and $\sigma_{\text{abs}} = 1$ mb (dotted-dashed curve), result with $\sigma_{\text{co}} = 0.65$ mb and $\sigma_{\text{abs}} = 3$ mb (dotted curve) and result with $\sigma_{\text{co}} = 0.65$ mb and $\sigma_{\text{abs}} = 4.5$ mb (full curve).
