**ARTICLE INFO**

**ABSTRACT**

Arsenic and nicotine exposure has been a major health concern globally. Individually both these toxicants increase the risk to various diseases including cancers. However, limited information exists on the co-exposure. In this study, we evaluate the effects of their individual and combined exposure and if co-exposure to these toxicants might have a synergism or antagonism. Male rats were exposed to a very low dose of arsenic (25 ppm in drinking water) or nicotine (0.25 mg/kg, sub-cutaneously) for a period of 5 months and post exposure various biochemical variables indicative of oxidative stress and apoptosis evaluated. Almost all glutathione linked enzymes showed marked alteration in individual as well as co-exposure treated groups. While serum creatinine and apoptosis indicator, lactate dehydrogenase (LDH) were significantly increased in both treatments, an additive effect was noted in co-exposure group. A similar trend was also seen in brain and liver but not in kidneys. Gene expression studies showed marked reduction in catalase, Cu-Zn SOD, GST, there was a significant up regulation in Bax, caspase 3 in various tissues along with urinary 8-OHdG levels, indicative of DNA damage and apoptosis. Interestingly, a decrease in liver arsenic concentration was noted in co-exposed group compared to arsenic alone exposed group. In conclusion, the present study suggests that arsenic and nicotine exhibited significant toxicity during individual exposure whereas co-exposure to these toxins showed variable conditions (indicative of both synergism and antagonism) in male rats.

1. Introduction

Arsenic is predominately present in water, soil, and air from natural and anthropogenic sources, however drinking of contaminated drinking water is the main cause of acute and chronic adverse health effects in humans [12,21]. Over 200 million people worldwide are at risk, of which more than 100 million are residing in West Bengal, India ([43] and Bangladesh); areas where groundwater arsenic concentrations exceed the World Health Organization maximum permissible level of 50 mg/L. [60]. Moreover, many states of United States too have reported significant arsenic groundwater concentrations (up to 50 ppm) [63,30]. Epidemiological studies have suggested a strong correlation between chronic arsenic exposure and various human diseases such as hyperkeratosis, atherosclerosis, diabetes, obstructive pulmonary diseases [12,64,63,44]. Long term arsenic exposure has also been linked to cancer of skin, lung, colon and rectal [70,22,29]. While the mechanism of arsenic induced toxicity is not clearly defined, several mechanisms have been proposed of which arsenic-induced oxidative stress is among most widely accepted and studied [12].

Nicotine, the most important constituent of tobacco, is responsible for habit forming properties of tobacco chewing and cigarette smoking. Nicotine poisoning produces nausea, vomiting, abdominal pain, diarrhoea, headaches, sweating, and pallor however, more severe poisoning results in dizziness, weakness, and confusion, progressing to convulsions, hypotension, and coma [28]. Like arsenic, nicotine also induces oxidative stress which ultimately results in several pathological conditions that needs further assessment. Although arsenic and nicotine have been studied individually many times, there are only a few co-exposure studies. We recently demonstrated that pre-exposure to nicotine before arsenic exposure revealed interesting toxicokinetic and oxidative stress modulating interactions in the brain and liver of rats [47]. Co-exposure studies have reported synergism between both compounds [17], impaired arsenic methylation and metabolism [19,34,33], increase risk of lung cancer [4,9] and oxidative stress [12,24]. Due to ever increasing exposure to these environmental
toxicants particularly in developing countries, there is increased interest to investigate the role of these toxicants individually and also interactive if co-exposure takes place [5]. In the present study we studied the individual and combined exposure to arsenic and nicotine on number of biochemical variables indicative of oxidative stress. Further we also studied if there is any synergism between arsenic and nicotine during co-exposure which would alleviate changes upon tobacco smoking in arsenicosis areas.

2. Material and method

2.1. Chemicals

Sodium meta arsenite was obtained from E. Merck (Darmstadt, Germany), nicotine as sodium hydrogen tartrate was procured from Sigma–Aldrich (St. Louis, MO, USA), while all other chemicals were of “Analar” or “Extra pure” grade and obtained from BDH chemicals (Mumbai, India), Merck (Darmstadt, Germany) or Sigma (St. Louis, MO, USA).

2.2. Experimental design

Forty-eight male Wistar rats (60–80 g, ~5 weeks) were obtained from the animal facility of Defence Research and Development Establishment (DRDE). They were maintained on ad libitum pellet diet (Lipton’s India Ltd) and water in an air-conditioned room with regular alternate cycles of 12 h light and darkness. The metal contents of the animal feed (in ppm dry wt.) were Cu 10, Mn 55, Co 5, Zn 45, and Fe 70. The animals were weighed every week and the doses were adjusted accordingly. All animals received humane care in compliance with the guidelines of the “Committee for the Purpose of Control and Supervision of Experiments on Animals (CPCSEA)”. The animals were acclimatized for 7 days prior to their use in experiments and were allowed a standard diet and water throughout the study. All 48 animals were randomized into 4 groups of 12 rats each and were treated as below for 5 months-

Group 1: Control (treated as normal and received normal water)
Group 2: Arsenic as sodium meta-arsenite (25 ppm in drinking water)
Group 3: Nicotine as nicotine dihydrogen tartrate (0.25 mg/kg body weight subcutaneously)
Group 4: Arsenic + Nicotine (same as in group 2 and 3, respectively)

After 5 months, rats were anesthetized under light ether and the blood samples were collected using a needle via intra-cardiac puncture to evaluate blood and serum biochemical variables after 15 days, 1 month and thereafter every month till the date of sacrifice. After 5 months, exposure was stopped and blood was collected in heparinized vials and serum was collected in non-heparinized tubes for biochemical estimation. Animals were quickly dissected under light ether anaesthesia, 24 h after the last dosing. Brain, liver and kidney was removed, washed thoroughly with chilled normal saline and stored at −80°C until use for biochemical estimation. Liver and brain tissue required for gene expression analysis are washed with ice cold DEPC (diethyl pyrocarbonate)–treated water to remove extraneous material and kept at −20°C in RNAlater®.

2.3. Biochemical assays

Amount of ROS in blood and tissues was measured using 2′,7′-dichlorofluorescin diacetate (DCF-DA) as described by Socci et al. [59]. Analysis of blood GSH concentration was performed by method of Ellman et al. [8] slightly modified by Jollow et al. [26]. Reduced glutathione (GSH) and oxidized glutathione (GS(G)) content in tissue samples were measured as described by Hissin and Hilf [18]. SOD activity was assayed by the method of Kakkar et al. [27]. Catalase activity in tissue was assayed following the procedure of Sinha et al. [57]. Measurement of lipid peroxidation was done by the method described by Ohkawa et al. [46]. Glutathione peroxidase was determined by the literature method [10]. GST activity was determined by Habig et al. [16]. Glutathione reductase was determined by the literature method of Worthington and Rosemeyer [68]. Glutamic oxaloacetic transaminase (GOT). Glutamic pyruvic transaminase (GPT), Urea, Creatinin and Lactate dehydrogenase (LDH) activities were measured in serum using Merck kits. 8-OHdG concentration in the urine was estimated using highly sensitive ELISA kit. Arsenic was estimated using a Hydride Vapor Generation System (PerkinElmer model MHS–10) fitted with an atomic absorption spectrophotometer (AAS, PerkinElmer model AAnalyst 100) by Parker et al. [49].

2.4. RNA isolation and RT-PCR

RNA stabilized whole brain was minced and 35 mg liver, 50 mg kidney and 75 mg of minced brain was used for RNA isolation. Total RNA was isolated from brain, liver and kidney as previous reported [39]. All RNA samples were stored at −80°C for further experiments.

Two micrograms of RNA was converted to cDNA using the First strand synthesis kit as described previously [38]. For semi-quantitative RT-PCR, 5 ng cDNA template was used for each sample and PCR was performed for 30 cycles 95°C for 15 s, varying annealing temperature for 30’s and 72°C for 30 s, with initial deactivation at 95°C for 5 min and final extension at 72°C for 7 min in GeneAmp PCR system 2700 (Applied Biosystems, USA). PCR products were electrophoresed on 1.5% agarose gel with ethidium bromide (Sigma–Arligh, MO, USA) and bands were visualized and recorded using Gelsdoc XR (Bio–Rad, Hercules, California, USA). List of primers used in the study are described in Table 1.

2.5. Statistical analysis

Experimental results were expressed as the mean ± SEM and were accompanied by number of observations. Data was assessed by the method of one-way analysis of variance (ANOVA) followed by Bonferroni test. Values with different symbols were significantly different from one another at the 5% level of probability.

3. Results

3.1. Effect on body weight index

Gain in body weight was recorded every week and the change in body weight (after completion of exposure—before exposure started) was presented in Fig. 1. There was significant decrease in the body weight gain in all the exposed groups as compared to normal animals.

3.2. Effect on blood oxidative stress variable

Individual arsenic and nicotine exposure in animals demonstrated consistent time dependent increase in blood reactive oxygen species (ROS) levels. However, in the combined exposure group, this increase was only observed up to 3 months with no further increase (Fig. 2). Interestingly, an increase after 15 days followed by subsequent decline up to 3 months in GSH was noted in all the exposed groups. After 3 months an elevated level of GSH was found in all exposed group. Blood TBARS levels increased at various stages of the study following various exposures, however, there was no particular trend observed (Fig. 2).

Co-exposure of As and nicotine demonstrated a significant increase in GPx activity by 1 month that continued till 3 months,

Body weight gain

Fig. 1. Effect of arsenic and nicotine on body weight index in exposed rats after 6 months.
Units: gain in body weight is expressed as grams (gms)
Values are mean ± SE; n = 5.
*p < 0.05 Compared to normal animals.

However, in individual treatment increased GPX activity was only noted by 3 months. However, GR activity demonstrated a significant increase in 1 month followed by a significant decrease in its activity. This increase at 1 month was mainly contributed by arsenic and not nicotine (Fig. 3). Unlike GPX and GR, GST levels remained significantly elevated throughout the study in individual as well as co-exposure groups (Fig. 3).

3.3. Effect on serum biochemical variables indicative of liver, kidney and membrane damage (Figs. 4 and 5)

There was a significant increase in SGOT, SGPT activity in all treated groups as compared to controls. However, the levels fluctuated over various time points but were highest at 5 months in all treated groups. Unlike SGOT and SGPT, LDH levels increased in a time dependent manner where the highest levels were reached by 5 months of exposure. Co-exposure of arsenic and nicotine showed more damage as compared to the individual treatments (Fig. 4). Arsenic, nicotine and co-exposed animals all showed an elevated urea level during the entire experimental period (Fig. 5). However, there was no time dependent trend observed. Likewise creatinine too showed an increased response following various treatments over the study period (Fig. 5).

3.4. Effect on 8-OHdG concentration in urine (Fig. 6)

There was an equal increase in urine 8-OHdG concentration upon arsenic or nicotine exposure. In the combination group, an elevated concentration of 8-OHdG was observed as compared to controls however, these levels were lower than the individual treatment groups.

3.5. Effect on brain biochemical variables (Table 2)

In brain, arsenic exposure led to a significant increase in ROS level and a decrease in enzymes regulating GSH and maintaining ROS balance, except GR suggesting oxidative stress. Interestingly, nicotine only affected GSH regulating enzymes (GPX and GR) more pronouncedly as compared to control animals during the exposure period. Co-exposure to arsenic + nicotine led to a more pronounced increase ROS and GSSG while to our surprise there was an increase in GSH level (Table 2).

3.6. Effect on hepatic biochemical variables (Table 3)

Most of the hepatic oxidative stress variables demonstrated marked alteration following treatment of arsenic and nicotine alone or in combination. However, there were subtle differences between the treated groups. While arsenic exposure alone did not significantly affect the levels of catalase, GR and GST, nicotine exposure alone depleted catalase and GR and increased GST levels (Table 3), suggesting differential effects of compounds.

3.7. Effect on renal biochemical variables (Table 4)

Renal oxidative stress variables indicated similar alterations in oxidative stress variables in all the exposed groups with an increase in ROS and TBARS on arsenic and nicotine exposure. On
the other hand there was a significant depletion in the level of GSH, GSH/GSSG ratio, catalase, GPx and GST activities. Interestingly, these changes during individual exposure do not led to a synergistic effects as there was increase in ROS but it was almost the same as in nicotine exposed group while there was only a marginal synergistic effects in GSSG and GSH/GSSG ratio. The changes in TBARS, catalase, GPx and GST were almost the same as observed with individual exposure.

3.8. Effect on arsenic concentration in blood and tissues (Fig. 7)

As expected, significant accumulation of arsenic was observed in blood and all tissues studied following chronic exposure to arsenic. However, co-exposure of arsenic and nicotine together demonstrated a highly significant arsenic accumulation in blood and kidney and a marked reduction in liver concentration in comparison to only arsenic exposed groups, indicating the influence of nicotine on the arsenic levels.
3.9. Effect on liver and brain antioxidant mRNA expression in rats (Figs. 8–10)

Brain catalase transcript level showed decreased expression but it was not statistically significant. Nicotine exposure on the other resulted in significant decrease in Cu-Zn SOD and GST transcript levels. No change in other mRNA expression of other antioxidants was however noted in brain.

Liver catalase, Cu-Zn SOD and MnSOD mRNA expression levels were down-regulated in co-exposed group compared to normal group. Arsenic exposure however led a down regulation of GPx transcript while no change in other groups were noted.
Fig. 4. Effect of co-exposure of arsenic and nicotine on GOT, GPT and LDH activity in serum.

*p < 0.05 Compared to normal animals.
† p < 0.05 Compared to arsenic exposed group.

3.10. Effect on liver and brain apoptotic gene mRNA expression in rats (Fig. 11)

There was an increase in hepatic Bax transcript level in all of the exposed groups but was more prominent in nicotine and co-exposed group as compared to controls. Hepatic Bcl2 (anti-apoptotic protein) and Caspase 3 mRNA expression also showed a slight down regulation in co-exposed group.

An increase in brain Bax expression in arsenic and co-exposed group along with an increased caspase 3 expression in co-exposed group was also observed. In con-
Fig. 5. Effect of co-exposure of arsenic and nicotine on urea and creatinine level in serum. Values are mean ± SE; n = 5.

Table 2
Effect of co-exposure of arsenic and nicotine on brain oxidative stress variables in rats.

|                | Normal | Arsenic | Nicotine | As + Nicotine |

Lane 1—Group 1 (Normal) Lane 2—Group 2 (Arsenic) Lane 3—Group 3 (Nicotine) Lane 4—Group 4 (Nicotine + As). *p < 0.05 Compared to normal animals.

A decreased Bcl2 mRNA transcript level was found in both the individually exposed arsenic and nicotine groups.

4. Discussion

Arsenic and nicotine are known to induce oxidative stress. Arsenic induces oxidative stress via generation of reactive oxygen species, reactive nitrogen species and also other reactive metabolites of arsenic such as dimethyl arsenic peroxyl radicals, dimethyl arsenic radicals etc [12]. Enhanced generation of reactive oxygen and nitrogen species is associated with a deficient antioxidant system leading to increased oxidative stress and is largely accepted as one of the common mechanisms of arsenic-induced neurotoxicity [48,11,56,58,6]. Arsenic is also known to induce carcinogenic effects in skin, lungs, liver, kidneys and bladder [66]. On the other hand, nicotine toxicity depends largely on the dose and duration of exposure. Exposure to a low dose and for a shorter duration exhibits antioxidant properties [41] while, prolonged exposure to a higher dose generates free radicals resulting in oxidative stress and reduction in antioxidant enzymes [15]. Interestingly, not only these compounds generated free radicals during their metabolism but also altered the gene expression levels of anti-oxidant enzymes [52,1,3,69]

Arsenic and nicotine individually and in combination demonstrated significant decrease in body weight which could be due to (i) increased metabolic rate [13], (ii) activation of lipoprotein lipase [67] or (iii) suppression of glycolysis [37]. We observed a significant increase in ROS in the exposed groups, however, animals co-exposed to arsenic and nicotine demonstrated comparatively less pronounced increase in ROS compared to the individual exposures, suggesting that effects on ROS were not cumulative but demonstrate largely antagonistic effects which may thus be attributed to a mechanism which currently is unknown and require further investigation.
Fig. 10. mRNA expression of β-actin (453 bp), catalase (452 bp), Cu–Zn SOD (201 bp), MnSOD (560 bp), GPx (221 bp) and GST (360 bp) in arsenic and nicotine exposed rat brain as compared with control after 6 months of exposure. * p < 0.05 Compared to normal animals.

Arsenic induced changes in glutathione have been reported previously [24,12]. All the exposed groups showed an initial increase in GSH concentration but gradually it started showing a decrease compared to normal animals. After three months of exposure GSH level again showed a marked increase suggesting an adaptive mechanism might have been developed. An increase in lipid peroxidation was observed in all the exposed groups and the changes were consistent throughout the duration of exposure [51,62]. Glutathione peroxidase and glutathione reductase activities showed a similar trend after month 1 and 3 in all exposed groups compared to normal animals. A moderate synergism however was noted in GPx activity after combined exposure to arsenic and nicotine. There was masking of nicotine effects by arsenic in the combination group in blood GR activity. An increase in GST activity in all the exposed groups may be attributed to the involvement of GST in arsenic and nicotine detoxification [25,65].

Elevated serum transaminases activities suggested hepatic injury. Elevated serum GOT activity was noted in all the exposed groups throughout the exposure period (from day 15 to 6 month) indicating liver injury. Interestingly, serum GPT activity decreased in animals co-exposed to nicotine and arsenic compared to normal, arsenic or nicotine group after day 15 and 2 month suggesting antagonism which needs to be explored further. Increased serum urea and creatinine levels indicated renal damage. Previous studies have reported arsenic or nicotine induced hepatic injury and renal dysfunction on continuous exposure [61,23,35,65,55]. Serum urea increased in all the exposed groups throughout the exposure period except in the first month when we noted a moderate decrease in
the combination group. A similar trend in the serum creatinin level was also noted. Lactate dehydrogenase activity in the serum is considered as marker of membrane damage, and it was found elevated on arsenic or nicotine exposure [32,42]. We noted no changes in LDH activity after day 15 and 3 months in any of the exposed groups studied. However, a similar trend was observed after month 1, 5 and 6. During this period there was a prominent increase in the serum LDH activity in the combination group as compared to individual exposed group.

8-oxo 2’ deoxy Guanosine (8-OHdG) concentration was evaluated in the urine as an indicator of oxidative DNA damage. An increased concentration of 8-OHdG in the urine suggest DNA damage. No difference however was noted between the exposed group. 8-OHdG has been reported to be marker for age related chronic diseases [50,31].

Brain biochemical variables suggested an increased oxidative stress in animals co-exposed to arsenic and nicotine compared to normal animals. Arsenic or nicotine induced increased brain reactive oxygen species and a decreased antioxidant level has been reported earlier [48,20]. We report no significant difference in the toxicity among the two exposed groups except the brain SOD activity exhibited a more pronounced depletion in co-exposed group compared to normal and individual exposed group. These findings are in consistent with the brain arsenic concentration which was same as in arsenic alone group. Semi quantitative gene expression analysis in the present study of certain antioxidant enzymes also indicated a decrease in the level of antioxidant mRNA transcript level in the exposed groups but the reason behind changes in the expression is not clear.
The extend of oxidative injury in brain of arsenic exposed animals was comparatively less pronounced compared to nicotine exposed group. Arsenic and nicotine induced hepatic injury particularly oxidative stress has been extensively studied \[12,7\] suggesting that both arsenic and nicotine induced oxidative stress targets liver. It was thus expected that the level of toxicity would be higher in combination group compared to individual exposure groups.

However, it was not seen in the present study possibly due to decreased uptake of arsenic in the co-exposed groups. Decreased liver arsenic level in co-exposed group is possibly due to nicotine induced altered arsenic metabolism. It has been reported earlier that all forms of tobacco use is associated with less efficient arsenic methylation as the smoking inhibits the specific AS3MT involved in arsenic methylation \[33\]. Cigarette smoking is also known to increase serum homocysteine concentration \[45,53\], which, via the concurrent accumulation of S-adenosylhomocysteine, exerts a strong inhibition of S-adenosylmethionine-dependent transmethylation reactions, including those of arsenic \[14,36\]. Smokers also tend to have lower levels of folate and vitamin B6 and B12 \[45\], which are essential for homocysteine metabolism and thus increasing its accumulation. Altogether, these alterations to decreased liver arsenic concentration in co-exposed group and thus less pronounced oxidative stress than expected. Liver antioxidant mRNA expression was also studied and the down regulation of certain antioxidant mRNA transcript was observed in arsenic and co-exposed group but the exact mechanism behind these alterations need to be understood. All of these changes ultimately resulted in decreased protein expression in liver of exposed groups.

Arsenic or nicotine exposure leads to renal oxidative stress during its metabolism suggesting nephrotoxicity \[2,54\]. In the present study, all the exposed groups showed renal injury in terms of increased oxidative stress. Increased kidney arsenic concentration in co-exposed group was also possibly due to nicotine induced altered arsenic metabolism in liver leading to enhanced elimination by kidney.

Arsenic or nicotine stimulated apoptosis was investigated in earlier studies and it was observed that both toxicans are responsible for apoptosis related cell death \[40,71\]. An increased liver Bax (apoptotic protein) mRNA expression in the nicotine alone and combination group compared to normal group suggest susceptibility to apoptosis in arsenic exposed group. On the other hand in the co-exposed group a slight decreased caspase 3 expression was found. A more detailed study is thus required to unequivocally establish the effects of combined exposure on apoptotic pathway. We observed an increased brain Bax level in arsenic and arsenic + nicotine co-exposed animals while, increased caspase 3 was noted in arsenic + nicotine co-exposed rat brain suggesting an increased apoptosis. However, we admit that apoptotic gene expression data did not provide a final conclusion.

To our knowledge this is the first study to suggest possible synergism between arsenic and nicotine co-exposed animals. However, this was established based only on few variables. Thus there is need to have a more detailed study to establish mechanism that nicotine is a major factor behind synergism earlier reported between tobacco and arsenic. We further suggest a possibility that other than nicotine there might possibly be other constituent(s) moieties responsible for the reported synergism. There was a significant alteration in antioxidant gene expression levels but the mechanisms behind these changes are not known. It can thus be concluded that both arsenic and nicotine if given individually or in combination are toxic at the present dose and duration. Further studies need to be done in this direction to study the exact mechanism behind synergism between arsenic and nicotine on oxidative stress or apoptosis.

Dose-response studies have been conducted in various animal species, including rats and mice, to evaluate the toxic effects of nicotine and its metabolites. For example, a study by Fuchs et al. (2013) investigated the role of nicotine in oxidative stress and DNA damage in Wistar rats. The study revealed that nicotine-induced oxidative stress and DNA damage were associated with increased expression of nicotinic receptors and altered DNA repair mechanisms.

In addition to oxidative stress, nicotine exposure has been shown to affect DNA methylation and transcriptional activity. For instance, a study by Suthukumar et al. (2008) demonstrated that nicotine-induced prooxidant and antioxidant imbalance and DNA damage in Wistar rats. The study suggested that nicotine exposure could alter DNA methylation patterns and transcriptional activity, leading to increased oxidative stress and DNA damage.

Nicotine-induced apoptosis in guinea pigs was studied by Pachauri et al. (2012), who observed that nicotine-induced neuronal apoptosis was dependent on the involvement of the mitochondrial pathway.

Overall, these studies highlight the importance of understanding the mechanisms by which nicotine induces oxidative stress and DNA damage in various animal species. Further research is needed to elucidate the complex interactions between nicotine exposure and the genetic and epigenetic pathways that regulate oxidative stress and DNA repair mechanisms.
