Abstract

Most of the literature on neural network quantization requires some training of the quantized model (fine-tuning). However, this training is not always possible in real-world scenarios, as it requires the full dataset. Lately, post-training quantization methods have gained considerable attention, as they are simple to use and require only a small, unlabeled calibration set. Yet, they usually incur significant accuracy degradation when quantized below 8-bits. This paper seeks to address this problem by introducing two pipelines, advanced and light, where the former involves: (i) minimizing the quantization errors of each layer by optimizing its parameters over the calibration set; (ii) using integer programming to optimally allocate the desired bit-width for each layer while constraining accuracy degradation or model compression; and (iii) tuning the mixed-precision model statistics to correct biases introduced during quantization. While the light pipeline which invokes only (ii) and (iii) obtains surprisingly accurate results; the advanced pipeline yields state-of-the-art accuracy-compression ratios for both vision and text models. For instance, on ResNet50, we obtain less than 1% accuracy degradation while compressing the model to 13% of its original size. We open sourced our code.

1 Introduction

The pursuit of advanced Deep Neural Networks (DNNs) causes researchers to construct deeper and wider networks, making them expensive to use in terms of power and time. This increases the need for efficient implementations of these networks. Efficient networks reduce cloud-vendor costs and make it possible to run them on low-power devices such as smartphones and wearable devices. The most common off-the-shelf approach to improving network efficiency is quantization, which reduces the numerical precision of the network and its complexity and memory footprint.

DNN quantization techniques can be classified as either pre-training or quantization-aware training techniques (Han et al., 2015; Courbariaux et al., 2015; Hubara et al., 2017; Zhou et al., 2016). Although quantization-aware techniques, in general, achieve better results, there are important real-world scenarios in which they are not applicable. These are cases where the training data is sensitive or simply unavailable at the time of deployment. For instance, when off-the-shelf or legacy models are being used, or when medical records are involved. Therefore, much attention has recently been dedicated to post-training quantization methods (Nagel et al., 2019; Banner et al., 2018; Zhao et al., 2019), which can be more easily applied in practice. These methods allow for network quantization...
to happen seamlessly when deployed, without requiring additional information from the user except a small unlabeled calibration set.

Unfortunately, post-training quantization below 8 bits usually incurs significant accuracy degradation. In this paper, our goal is to reduce the storage and energy required to run inference on large networks in this challenging but practical use-case. To achieve this goal, we suggest a three-stage pipeline that consists of methods to reduce the local error introduced during the quantization process (e.g., round-off errors) followed by integer programming to determine the precision of different layers so that overall accuracy degradation is minimized.

Even without using mixed-precision, the suggested method (aimed for per-channel quantization of the weights) yields best in class results for 8-bits Mobilsnet-V2 and BERT-base trained on ImageNet and SQuAD1.1 datasets respectively.

Our contributions

Our paper suggests several contributions for mixed-precision post-training quantization:

1. **AdaQuant**: A layer-by-layer optimization method that minimizes the error between the quantized layer output and the full-precision layer output. This method can consume only a small calibration dataset from training data without overfitting. In a comprehensive study, we show that AdaQuant defines a new state-of-the-art for post-training quantization on several networks and tasks, including vision models (Resnet18, Resnet50, MobilenetV2) and language (BERT).

2. **Integer programming**: As some parts of the network may allow lower precision compared to other layers, we suggest integer-linear programming based approach for determining the precision level of different layers. This method aims at maximizing either the expected speedup or savings in power consumption without violating a predefined constraint on network accuracy degradation or compression.

3. **Batch-norm tuning**: We observe an inherent bias in the mean and the variance of batch norm statistics following their quantization. The bias in this statistic causes a significant accuracy degradation and we suggest a simple method to compensate for it. We show that by employing the re-estimated statistics in batch normalization, much of the quantized network degradation can be recovered.

4. **Light and Advanced pipelines**: We analyze the advantages and disadvantages of each of the given methods and suggest two pipelines: (1) light pipeline that does not require a backward pass, thus can be invoked even on inference-only hardware; and (2) Advanced pipeline that includes also AdaQuant and bias tuning.

2 Related work

There has been a significant effort by many researchers to compress models via quantization (Courbariaux et al., 2015; Han et al., 2015; Rastegari et al., 2016; Zhou et al., 2017). These works involve re-training in order to compensate for the degradation due to the quantization process. Post-training quantization, on the other hand is applied to a model after it was trained. Thus, it avoids re-training and as such it is much simpler to use. However, naively quantizing a full-precision model to INT4 and lower usually incurs significant accuracy degradation (Krishnamoorthi, 2018; Jacob et al., 2018).

**AdaQuant**: A recent post-training quantization method (Nagel et al., 2020), termed AdaRound, suggested optimizing the rounding policy. Instead of using the predominant rounding-to-nearest approach, they suggest formulating a per-layer quadratic optimization problem to optimize the round-off error. Our proposed method, AdaQuant, takes another step and relaxes AdaRound implicit constraint which forces the quantized weights to be within ±1 of their round-to-nearest value. This is done by optimizing the weights and quantization parameters of each layer separately, over the calibration set, to minimize the MSE distance between the layer’s original and quantized outputs.

**Integer programming**: Aflalo et al. (2020) used a combinatorial optimization approach for network pruning. Their problem was formulated as a Knapsack problem that optimizes the trade-off between the importance of channels and their associated computational cost. Cai et al. (2020) finds a mixed-precision configuration with a guaranteed Pareto efficient allocation with respect to model size and accuracy degradation. While this provides a "best-effort" standard (e.g., the configuration cannot be
further compressed without hurting accuracy), it does not suggest which of all possible outcomes is best. To the best of our knowledge, this work is the first to formalize a generic integer programming formulation, which can easily be adapted to various types of models and requirements with a clear objective and constraints.

**Batch norm tuning:** Finkelstein et al. (2019) were the first to recognize that a significant source of degradation is a shift in the mean activation value. They show a simple method to compensate for this bias by updating the bias terms. Nagel et al. (2019) suggest to equalize the weight ranges in the network and correct biases in the error that are introduced during quantization.

3 Optimizing Quantization Pipeline

In most post-training quantization settings, a model and a small unlabeled calibration set are given. To avoid overfitting the calibration set, most studies utilize it only to extract the network’s internal statistics, which is later used to set the quantization parameters. Here we suggest using the calibration set much more extensively to tune the model; since we tune the model layer-by-layer, we are less prone to overfitting.

In the following subsections, we detail three different optimization methods over the calibration set: (1) AdaQuant, a layerwise MSE optimization of weights and quantization parameters to reduce the layer’s output distortion; (2) an integer programming formulation for the mixed-precision setting; and (3) Batch Normalization Tuning (BNT), for tuning the model internal statistic to match the numerical precision setting. Next, we discuss the strengths and weaknesses of each method and suggest an optimization flow that exploits all the additive merits and leads to state-of-the-art results.

3.1 AdaQuant - Layerwise Optimization over the Calibration Set

Several researchers suggest per-tensor optimization to reduce quantization error by minimizing some form of MSE objective between the quantized and the full-precision tensor $X$ (either weights or activations). They look for an optimized quantization step size $\hat{\Delta}$ obtained by

\[
\hat{\Delta} = \arg \min_{\Delta} ||X - Q_\Delta(X)||^2
\]

where $Q(\cdot)$ is the quantization function,

\[
Q_\Delta(X) = \Delta \cdot \left\lfloor \frac{X}{\Delta} \right\rfloor
\]

Although these methods are fast and easy to use, they often result with an inferior solution since the loss in eq. (1) is sub-optimal: what we actually care for is the classification error at the network’s output, so we should penalize more quantization errors which can affect this output. Taking a step in this direction, by noting the classification error is only a function of the pre-activation in the following layer, we use instead a modified objective:

\[
\left(\hat{\Delta}_w, \hat{\Delta}_x\right) = \arg \min_{\Delta_w, \Delta_x} ||WX - Q_{\Delta_w}(W) \cdot Q_{\Delta_x}(X)||^2
\]

Notably, this loss also takes into the account interactions between quantization errors of the weights and activations, in contrast to eq. (1) Additionally, in this new objective the quantized tensor is not required to be "close" to the original tensor, as in eq. (1). Thus, we get an additional degree of freedom which we exploit in AdaQuant. Specifically, we suggest training also over a continuous variable $V$ added to $W$

\[
\left(\hat{\Delta}_w, \hat{\Delta}_x, \hat{V}\right) = \arg \min_{\Delta_w, \Delta_x, V} ||WX - Q_{\Delta_w}(W + V) \cdot Q_{\Delta_x}(X)||^2
\]

and the quantized network weights are defined as $W_q = Q_{\hat{\Delta}_w}(W + \hat{V})$. AdaQuant also optimizes over biases and offsets; these were removed from the formulation in Equation (4) for simplicity.
Size of calibration set Perhaps surprisingly, although we experiment with a very small calibration set, no overfitting is observed. We analyze the reason AdaQuant does not overfit on a small calibration set and give a simple equation that defines the required size of the calibration set for AdaQuant to succeed. Since we train using AdaQuant over a very small set of samples, one has to wonder why the model does not overfit the data. Let us examine a simple fully connected layer $W \in \mathbb{R}^{N \times M}$. The input and output are of sizes $N$ and $M$, respectively. If we have $B$ unique samples, then the total number of equations we have to solve is $B \cdot M$, each with $M \cdot N$ parameters. Therefore if $B \ll N$ we generically have an infinite amount of solutions and we can overfit the data.

If $B \gg M$ then we might underfit the data. Thus, the size of the calibration set required for AdaQuant should roughly be $O(M)$. For convolution layers the number of features is of dimensions $C_i \times C_o \times k \times k$ and the output of the layer is of dimensions $B \times C_o \times H \times W$. Therefore, to avoid overfitting the calibration size should have $B \geq \frac{C_i k^2}{HW}$ samples. Figure 1 demonstrates the robustness of AdaQuant to the calibration set size. Remarkably, AdaQuant does not overfit even when optimized on a single image.

3.2 Integer programming formulation

AdaQuant significantly enhances network accuracy at lower bit widths. However, they are often not sufficient by themselves to attain acceptable accuracy. Therefore, in practical use cases, the user would like to balance between accuracy and performance (e.g., power and speed), by setting several layers to higher precision. Our high-level goal in this section would be to optimize the overall network performance, while maintaining a predefined accuracy degradation or a model compression constraint.

In the following, we provide an integer-programming formulation for optimizing per-layer bit allocations. Depending on the needs, our performance metrics $\mathbb{P}$ would be either the execution time of the network or its power consumption. Also, with every layer quantization, there is an associated quantization error that affects the training loss $L$. We chose the latter to be our penalty metric.

Basic formulation We are given a neural network with $L$ layers. For each layer $l$, we have weights $W_l$ that need to be multiplied with activations of the previous layer $X_{l-1}$. Such lower bit width multiplications can be executed by quantizing the weights and activations to achieve higher throughput and energy-efficient solutions. Let $W_i^k$ and $X_{i-1}^n$ represent a quantized version of $W_i$ and $X_{i-1}$ to $k$ and $n$ bits, respectively. For each layer $i$, a low-bit width multiplication $W_i^k \cdot X_{i-1}^n$ results with a degradation in the loss $\Delta L_{i,n}^{k}$ and in performance improvement $\Delta \mathbb{P}_{i,n}^{k}$ with respect to the original product $W_l \cdot X_{l-1}$. This performance improvement measure needs to be additive and sum up to a total benefit in end-to-end network performance (e.g., power, model size, etc.). Our goal would be to maximize the total performance improvement without exceeding the total network degradation $\Delta L$.

We now turn to solve the above problem using an integer program. We define a binary variable $I_{i,n}^{k}$, which is set to one if and only if the weights $W_i^k$ are multiplied with the activations $X_{i-1}^n$ at layer $l$; otherwise we set the indicator to zero i.e., $I_{i,n}^{k} = 0$. Then, the basic bit allocation problem can be
formulated as follows:

\[
\text{Maximize } \quad \sum_{l=0}^{L-1} \Delta P_l \\
\text{Subject to } \quad \sum_l \Delta L_l \leq \Delta L, \\
\forall l \in \{1, ..., L\} : \Delta P_l = \sum_{k,n} I_{k,n}^l \cdot \Delta P_{k,n}^l, \Delta L_l = \sum_{k,n} I_{k,n}^l \cdot \Delta L_{k,n}^l
\]

(1) \quad (2) \quad (3) \quad (4)

The objective function (1) maximizes the total performance improvement. Constraints (2) and (3) ensure that the total degradation in loss and the total improvements in performance due to the quantization of layer \( l \) to \( k \)-bit-weights and \( n \)-bit-activations would be \( \Delta L_l \) and \( \Delta P_l \), respectively. Equation (4) states that the restriction on total degradation of \( \Delta L \) is obeyed and ensures that only one configuration (of quantized weights and activation) per layer is selected.

### 3.3 Batch Normalization Tuning

A common practice is fusing BN layers into their predecessor weight layers before applying post-training quantization to reduce the amount of MAC operations. However, the reduction in bit-width after quantization can cause the model internal statistics to deviate further from those of the full precision model. To compensate for this deviation, we suggest updating BN statistics. First, we need to reconstruct the BN layers then re-tune the BN layers’ statistics (by a few iterations of running-mean to re-collect the statistics). Finally, re-absorb (re-fuse) the BN layers into the weight layers (this is possible only in a per-channel weights quantization setting, which is the current standard). Next, we give more details on each phase.

**Reconstructing BN layers:** Assume the original (pre-fusing) BN parameters \( \gamma_o, \beta_o \) and \( \epsilon \) are known, as is usually the case. We would like to initialize \( \mu, \sigma^2 \), as well as the BN parameters \( \gamma_r, \beta_r \) (\( r \) for "reconstructed") so that the reconstructed BN

\[
BN_r(x) = \gamma_r \frac{x - \mu}{\sqrt{\sigma^2 + \epsilon}} + \beta_r \approx x
\]

will re-adjust the model statistics. To do so, first we initialize the reconstructed BN layers by setting the following parameters (denoted by \( r \)):

\[
\mu = \beta_r = \beta_o; \quad \sigma^2 = \gamma_o^2; \quad \gamma_r = \sqrt{\gamma_o^2 + \epsilon}
\]

so that \( BN_r(x) = x \). Then, we update \( \mu \) and \( \sigma^2 \) by collecting running mean and running variance on the calibration data. We stress that the BN parameters, \( \gamma_r, \beta_r \), do not change while applying BN tuning, as we only invoke forward propagation.

**Re-fusing BN layers:** Due to the per-channel quantization setting we use, the collected statistics can be fused back into the current quantization scale as follows:

\[
W_i' = W_i \frac{\gamma_r}{\sigma} \quad b_i' = \frac{\gamma_r}{\sigma} (b_i - \mu) + \beta_r; \quad \Delta w_i' = \frac{\gamma_r}{\sigma} \Delta w_i
\]

Thus, in addition to the regular BN fusion, the quantization step are adjusted by \( \gamma_r, \sigma^{-1} \). Additional details are given in Appendix A.

**Bias tuning** Much like Finkelstein et al. (2019), we suggest to apply a global bias-tuning procedure on the final mixed-precision model by applying quantization-aware training to minimize the Knowledge Distillation (KD) loss (which does not require labels). Since we restrict the trainable variables to be the biases only, we can train only on the calibration set without experiencing overfitting.
4 Post-training Quantization Flow

Past years have seen the rapid development of efficient deployment techniques (Nagel et al., 2019; Haroush et al., 2019). Deployment flows can vary based on the user setting such as hardware constraints, deployment time and task/dataset availability. While some users are willing to pay at initialization the time and effort to gain another fraction of accuracy, others require a simple and fast solution. We address this by suggesting two novel pipelines, light and advanced. Our pipelines are designed to the current, most common setting: per-channel quantization with a small calibration set.

Our light pipeline requires three steps: (1) Fuse layers and define quantization parameters; (2) Find optimal mixed-precision configuration using IP; and (3) Use BN tuning to correct the internal statistics. We note that all steps do not require back-propagation and thus are very light and fast. In addition to the light setting, in the advanced pipeline we apply AdaQuant to reduce each layer’s output distortion from its full precision counterpart before invoking the IP algorithm. Models that were optimized using AdaQuant to different bit-widths can be seamlessly stitched thus having the ability to create an optimized model in a mixed precision setting. Subsequently, global methods such as tuning both BN statistics and the layers’ biases can be applied to reduce a Knowledge Distillation loss. Although there are additional post-training quantization techniques that could be potentially combined with our methods, such as bias correction (Banner et al., 2018), equalization (Meller et al., 2019), and outlier channel splitting (Zhao et al., 2019), we did not find it necessary: our results demonstrate that our relatively simple pipeline yields state of the art accuracy on both vision and text models, even without combining such methods. In the following sections we show our findings and give an ablation study that highlights the importance of each method and their combination.

5 Experiments

In this section, we demonstrate our methods and pipelines on several models and datasets. We first start by analyzing image recognition models such as ResNet18/50, MobileNet-V2, which were trained over the ImageNet dataset. Next, we demonstrate the our method robustness by applying it on question answering task using the popular BERT model (Devlin et al., 2018), which was fine-tuned on SQuAD1.1 dataset (Rajpurkar et al., 2016). In all our experiments, we used a small calibration set taken from the training dataset. Unless stated otherwise, we applied asymmetric per-channel quantization (i.e. GEMLOWP Wu et al. (2016)) with quantized offset (i.e., zero point). Next, we analyze each method’s strengths and weaknesses separately and argue for its validity. Additional implementation details can be found in Appendix B.
5.1 AdaQuant

Recently several researchers suggested different types of MSE optimization. In most cases, the optimization was done per-tensor (i.e., for the weights and activations separately). Here we argue that by optimizing both quantization parameters and the weights jointly, we can reduce the MSE even further and hence improve the accuracy as demonstrated in fig. 3b. In contrast to AdaRound (Nagel et al., 2020) which restricted the change of the weights to be within $\pm 1$, we allow the weights to change as needed. As can be seen in fig. 3a, the weights indeed change their quantized value by more than one. Since our pipeline is focused on the mixed-precision setting, we optimize each layer separately to enable maximum flexibility when stitching the optimized models. Testing the strength of this method on both vision and text topologies resulted with state-of-the-art results. As can be seen in table 1, on BERT-base model we managed to obtain 81.17% exact match using just AdaQuant — less than 0.5% of its full precision counterpart (81.3%).

![Figure 3: AdaQuant vs. AdaRound. (a) A histogram of $\Delta W$ distribution. AdaRound restricts this additive term to be $\Delta W = \pm 1$. Relaxing this constraint provides a more powerful optimization. (b) Optimizing different parameters results with different accuracy degradation (ResNet50 on ImageNet). AdaRound is based exclusively on weight optimization, while AdaQuant optimizes the weights, biases, and other quantization parameters jointly.](image)

5.2 Integer Programming

Our Integer programming formulation requires us to have two quantities per-layer: (1) loss degradation and; (2) performance improvement. Obtaining those quantities requires to invoke the model over a small calibration set $L$ times (once per layer) and measure the loss degradation and the performance gain. In our experiments, we set the performance value to be the number of parameters, but this measure could be changed to any additive measure. In all experiments, we used 1000 samples from the training set as our calibration set. Our setting considers only a mixture of 8-bit and 4-bit layers; to further test IP capabilities, we investigate mixture of 2-4-8 bits as well. Unfortunately, since 2-bits quantization in post-training setting results with high degradation, the IP algorithm chose only mixture of 4-8 bits for compression ratio higher than 12.5%. Yet for 12.5% compression ratio, IP method found that by setting one layer to 2-bits while setting 8 smaller layers to 8-bits accuracy gains over 5.5% with respect to uniform 4-bit quantization. Also, by allowing a less hardware friendly setting where numerical precision can have the form of any integer between 2-8, results with the highest compression-accuracy ratio fig. 2 - relaxed advanced pipeline. In the last section, we compare the configurations found by IP method to several strong baselines.

5.3 BN Tuning

BN Tuning (BNT) has an significant advantage, as it does not require weight optimization. However, because it is applied by invoking the entire model, once the model is optimized, changing the bit-widths of the different layers will result in a degradation in model accuracy. This property is similar to all global tuning methods, including bias tuning. Thus, both BNT and bias tuning should be applied after setting the mixed-precision configuration. BNT requires only a few (at most 10) forward passes...
over the calibration set and yield significant gains as can be seen in our vision experiments (fig. 4). In this study, we applied BNT on models trained with BN layers only. However, it could be possible to extend this method to models without Batch Norm by reconstructing it from the statistics. We encourage the reader to investigate this path as it may lead to significant benefits.

5.4 Full pipeline and ablation study

Although several researchers suggested different methods for post-training mixed-precision quantization, none offer their code. Each paper focuses on a different quantization setting (e.g., quantizing only the weights, per-tensor quantization, etc.). Therefore, to demonstrate our pipeline strength, we created two different baselines based on common practices:

- Greedy-accuracy: recent studies suggested measuring each layer sensitivity and, based on the compression target, reduce the precision for the most robust layers.
- Greedy-compression: the complementary greedy approach to sort the layers by their number of parameters and increase the precision of the layers from the smallest to the largest layer until the compression budget is reached.

Surprisingly, although the size of the layer should correlate with its sensitivity to quantization, the two greedy methods yield entirely different configurations. Investigating the configuration greedy-compression found that sorting by compression correlates with the location of the layers in the model. In most vision models, the layers closer to the input have fewer parameters. This aligns with current common practice (Banner et al., 2018). Notably, even when not combined with any other technique, the IP method obtained the best bit-width configurations stressing its importance.

Next, we turn to consider the light and advanced pipelines. Under challenging compression rates, our light-pipeline results highlight the importance of BN tuning. As can be seen in our experiment fig. 2 and fig. 4 by merely invoking the model at inference mode for a few iterations and fixing the intermediate statistics, one can recover more than 1% of the accuracy (73.7% v.s 74.5%). As expected, by applying the advanced pipeline, one can obtain state-of-the-art accuracy. Arguably, our most impressive results are at 0.13% compression rate in which we managed to stay within 1% of the full precision accuracy while converting 96% of the model to 4-bit. Since most recent papers do not show full compression-accuracy curves, we also compare our results to common fixed configurations. Tables 1a and 1b indicate that combining AdaQuant with BN and bias tuning yields the best-in-class results for all models tested. For instance, on the extensively studies 8bit MobileNet-V2 topology we achieved 71.6% top-1 accuracy — less than 0.5% degradation compared to the full precision counterparts (71.9%).

| Method          | ResNet-18 | ResNet-50 |
|-----------------|-----------|-----------|
| ACIQ* (clipping)| 44.5%     | 60.9%     |
| DFQ* (clipping) | 56.1%     | 64.5%     |
| Ours            | 67.5%     | 73.7%     |
| FP32            | 69.7%     | 76.1%     |

(a) Comparison between post-training quantization methods. All layers were quantize to 4-bit except first and last layers which were set to 8-bit. Methods marked with (*) were implemented in our setting according to the paper.

| Method | MN-V2 | BERT-B-SQ1.1 |
|--------|-------|--------------|
| min-max| 70.9% | 80.22        |
| DFQ    | 71.2% | N/A          |
| Ours   | 71.6% | 81.17        |
| FP32   | 71.8% | 81.3         |

(b) Comparison with DFQ and naive quantization methods. Where the naive method uses the channel’s full dynamic range. In our experiments all layers where quantized to 8-bit.

Table 1: Quantization methods comparison at Int4 setting (a) and Int8 setting (b). In all our experiments we are apply per-channel quantization of the weights. At the Int4 setting, the first and last layers were quantized to 8-bit.
Figure 4: ResNet-18 and MobileNet-V2 - compression-accuracy curves

A Reconstruction and re-fusing of Batch Normalization

In this section we provide more details on Batch Normalization reconstruction and re-fusing procedure.

**Reconstructing BN layers:** Consider a Batch Normalization layer with parameters $\gamma_o, \beta_o$ that fused into previous convolutional layer weight and bias. Fusing batch normalization layer transforms weights and bias as following:

\[
W'_i = W_i \frac{\gamma_o}{\sigma}; \\
b'_i = \frac{\gamma_o}{\sigma}(b_i - \mu) + \beta_o; \\
\]

To reconstruct the batch normalization, we would like to initialize $\mu, \sigma^2$ as well as the BN parameters $\gamma_r, \beta_r$ (r for ’reconstructed’) so that the reconstructed BN is approximately identity fig. A.1.

\[
BN_r(x) = \gamma_r \frac{x - \mu}{\sqrt{\sigma^2 + \epsilon}} + \beta_r \approx x \\
\]

To do so, first we initialize the reconstructed BN layers by setting the following parameters (denoted by r):

\[
\mu = \beta_r = \beta_o; \\
\sigma^2 = \gamma^2_o; \\
\gamma_r = \sqrt{\gamma^2_o + \epsilon} \\
\]

so that $BN_r(x) = x$.

Now, we can update $\mu$ and $\sigma^2$ by collecting running mean and running variance on the calibration data. We stress that the BN parameters, $\gamma_r, \beta_r$, do not change while applying BN tuning, as we only invoke forward propagation.

**Re-fusing BN layers:** After BNT phase we need to fuse Batch Normalization layer again into convolution weights and bias. Regular batch normalization fusing will cause degradation due to quantization of the weights. To resolve this issue we can leverage per-channel quantization setting we use.

Denote $s_{w_i}, z_{w_i}$ scale and zero point of the weigh, the quant/dequant operation defined as:

\[
W_q = s_{w_i} \left( \left\lfloor \frac{W}{s_{w_i}} - \frac{z_{w_i}}{s_{w_i}} \right\rfloor + \frac{z_{w_i}}{s_{w_i}} \right) \\
\]

11
We can fuse parameters of the batch normalization layer as following:

\[
W'_i = W_i \frac{\gamma_r}{\sigma_x}; \quad b'_i = \frac{\gamma_r}{\sigma_r} (b_i - \mu_x) + \beta_r
\]

\[
s'_{w_i} = \frac{\gamma_r}{\sigma_x} s_{w_i}; \quad z'_{w_i} = \frac{\gamma_r}{\sigma_x} z_{w_i}
\]

(A.12)

Finally we can show that transformations eq. (A.12) equivalent to \(\frac{\gamma_r}{\sigma_x} W_q\)

\[
W'_q = s'_{w_i} \left( \frac{W'}{s'_{w_i}} - \left[ \frac{z'_{w_i}}{s'_{w_i}} \right] \right) + \frac{z'_{w_i}}{s'_{w_i}}
\]

\[
= \frac{\gamma_r}{\sigma_r} s_{w_i} \left( \frac{W}{s_{w_i}} - \left[ \frac{z_{w_i}}{s_{w_i}} \right] \right) + \frac{z_{w_i}}{s_{w_i}}
\]

(A.13)

**B Experiments Setting**

In all our experiments, we used a small subset of the training set to run our methods. Specifically, for vision models, we used 1000 unlabeled images from the ImageNet training set (single image for each class) as a calibration set. For Bert model, we used one paragraph from the training set. All presented methods AdaQuant, BNT, BT, and IP, performed well on such small calibration set producing SOTA results. Next we detail our setting for each of the technique in our pipelines.

**B.1 AdaQuant**

AdaQuant optimization problem defined as following except zero-point of the quantizer which we omitted from eq. (B.14):

\[
\left( \hat{\Delta}_w, \hat{\Delta}_x, \hat{V}_W, \hat{V}_b \right) = \arg \min_{\Delta_w, \Delta_x, V_W, V_b} \|WX + b - Q\Delta_w (W + V_W) \cdot Q\Delta_x (X) - Q(b + V_b)\|^2
\]

(B.14)

Technically to find a solution for eq. (B.14), we use Adam optimizer with different learning rates per type of parameters. We set different learning rates for weight, bias, and quantization parameters of input and weights. After experimenting with different models, we found that the same set of LR parameters worked for each model. The learning rates are \(1e-5, 1e-3, 1e-1, 1e-3\) for weight, bias, quantization parameters of the inputs, and weights, respectively.

For vision models, we used 1000 unlabeled images from the ImageNet training set (single image for each class), running Adam optimizer for 100 iterations and a batch-size of 50 unless otherwise stated. For BERT-base model, we used one paragraph from the training set, running Adam optimizer for 50 - 100 iterations depending on the type of layer. Learning rates and batch size are the same as of vision models.

**B.2 Integer Programming**

Our IP method requires two steps, the first is measuring the properties of each layer, and the second is applying the program based on these measurements with user defined constraint. As reference, we measure the loss (can also be accuracy) of the base precision model on the calibration set. Next, we measure the sensitivity of each layer by evaluating a model where all layers are quantize to the base-precision but one layer that is quantized to lower precision (e.g., all 8-bit but one layer with 4-bit). The \(\Delta L_i\) in Eq. 3 is defined as the difference between the reference model loss and the measured loss. I.e. if a layer is robust to quantization, \(\Delta L_i\) will be small, and if a layer is sensitive
to quantization, $\Delta L_l$ will be large. The performance gain in the case of compression, is simply the model parameters size difference when lowering the precision of the examined layer. Hence, if a layer has $N$ parameters, the performance gain when changing from 8-bit to 4-bit result with compression gain of $\Delta P_l = N \times 8 - N \times 4 = 4N$. In the second stage, we run the integer program based on the sensitivity and compression measured on each layer along with the user defined constraint.

B.3 Batch Normalization and Bias Tuning

The Batch Norm tuning phase is the most lightweight phase of the pipeline. We found empirically less than ten iterations of statistics update is sufficient. We also found that as compression growth, more iterations of batch norm tuning required. At the bias tuning phase, we perform 200 iterations of fine-tuning with the learning-rate of 0.1.

C Code

For all our vision dataset we used the default torchvision pre-trained model. For BERT-base experiment we fined-tuned on SQUAD1.1 dataset and provide the script for that as a part of our repository.
