Liquid-gas phase diagram for the dipolar hard-sphere fluid was calculated theoretically more than thirty five years ago by Rushbrooke et al. \cite{1}. According to these calculations the critical point is located at reduced temperature $T^*_c = 0.279$ and reduced density $\rho^*_c = 0.159$. Systematic computer simulation search for the liquid-gas phase coexistence was initiated only twenty years later \cite{2,3}. These investigations were carried out at temperatures well beyond predicted theoretically, however no evidence for the phase transition was found. Shortly after there appeared a number of the theoretical papers, in which the arguments were given as to why the existence of the liquid-gas phase transition has to be ruled out. It was suggested that due to the highly anisotropic character of the dipole-dipole interaction the formation of the chains in the `nose-to-tail' arrangement suppresses the liquid-gas phase transition. However, recent computer simulation \cite{4}, carried out for the temperatures lower than those studied earlier, presented the evidence for the phase transition with the critical point located at $T^* \approx 0.15 - 0.16$ and $\rho^* \approx 0.1$.

We present and discuss the liquid-gas phase diagrams of the monodisperse and polydisperse versions of the dipolar hard-sphere fluid, calculated using thermodynamic perturbation theory for associative fluids with center-center type of interaction \cite{5,6}.
