Abstract. We present a detailed analysis of a high resolution spectrum of the damped Ly$\alpha$ system at $z_{\text{abs}} = 2.8112$ toward PKS 0528-250. The absorption redshift is slightly larger than the emission redshift of the quasar. We estimate the column density of H$_2$ molecules $N$(H$_2$) $\sim$ 6$\times$10$^{16}$ cm$^{-2}$ and the fractional abundance of H$_2$, $f = 5.4 \times 10^{-5}$. The excitation temperature derived for different transitions suggests that the kinetic temperature of the cloud is $\sim$200 K and the density $n \sim 1000$ cm$^{-3}$. The cloud therefore has a dimension of $\sim$1 pc along the line of sight. Since it obscures the broad-line emission region, its transverse dimension should be larger than 10 pc.

We obtain upper limits on the column densities of C$^1$ ($< 10^{12.7}$ cm$^{-2}$) and CO ($< 10^{13.2}$ cm$^{-2}$; $N$(CO)/$N$(H$\alpha$) $< 7 \times 10^{-9}$). We suggest that the ratio $N$(H$_2$)/$N$(C$^1$) is a useful indicator of the physical conditions in the absorber. Simple photo-ionization models assuming solar relative abundances show that radiation fields with spectra similar to typical AGNs or starbursts are unable to reproduce all the constraints and in particular the surprisingly small $N$(C$^1$)/$N$(H$_2$) and $N$(Mg$^1$)/$N$(H$_2$) ratios. In view of the models we explored, the most likely ionizing spectrum is a composite of a UV-"big bump" possibly produced by a local starburst and a power-law spectrum from the QSO that provides the X-rays. Dust is needed to explain the production of molecules in the cloud. The amount of dust is broadly consistent with the [Cr/Zn] abundance determination.

1. Introduction

QSO absorption line systems probe the baryonic matter over most of the history of the Universe ($0 < z \lesssim 5$). The so-called damped Ly$\alpha$ (hereafter DLA) systems are characterized by a very large H$\alpha$ column density ($N$(H$_\alpha$) $\gtrsim 2 \times 10^{20}$ cm$^{-2}$), similar to the one usually seen through local spiral disks. The case for these systems to be produced by proto-galactic disks is supported by the fact that the cosmological density of gas associated with these systems is of the same order of magnitude as the cosmological density of stars at present epochs (Wolfe 1996). Moreover, the presence of heavy elements ($Z \sim 0.1 Z_\odot$) and the redshift evolution of metallicity suggest the ongoing star formation activities in these systems (Pettini et al. 1997), while strong metal line systems have been demonstrated to be associated with galaxies at low and intermediate $z$ (e.g. Bergeron & Boissé 1991). It has also been shown that the profiles of the lines arising in the neutral gas show evidence for rotation (Wolfe 1996, Prochaska & Wolfe 1997). Whether these arguments are enough to demonstrate that DLA systems arise in large disks is a matter of debate however. Indeed simulations have shown that the progenitors of present day disks of galaxies could look like an aggregate of well separated dense clumps at high redshift. The kinematics could be explained by relative motions of the clumps with very little rotation (Haehnelt et al. 1997, Ledoux et al. 1998). Moreover, using HST high spatial resolution images of the field of seven quasars whose spectra contain DLA lines at intermediate redshifts ($0.4 \lesssim z \lesssim 1$), Le Brun et al. (1996) show that, in all cases, at least one galaxy candidate is present within 4 arcsec from the quasar. There is no dominant morphological type in their sample: three candidates are spiral galaxies, three are compact objects and two are amorphous low surface brightness galaxies. Therefore, although the nature of the DLA systems is unclear they trace the densest regions of the Universe where star formation occurs.
It is thus surprising that despite intensive searches, the amount of H$_2$ molecules seems quite low in DLA systems in contrast to what is observed in our own galaxy. Two detections of H$_2$ molecules in high redshift DLA systems have been reported. Recently Ge & Bechtold (1997) have found strong absorptions in the DLA system toward Q 0013–004. They derive $N$(H$_2$) = 6.9×10$^{19}$ cm$^{-2}$, $b$ = 15 km s$^{-1}$, $T_{ex}$ ∼ 70 K and $n$(H) ∼ 300 cm$^{-3}$ for a total hydrogen column density $N$(H) = 6.4×10$^{20}$ cm$^{-2}$. This system has by far the largest H$_2$ abundance $f = 2N$(H$_2$)/[2N(H$_2$) + N(H I)] ∼ 0.22±0.05 observed in high z DLA systems. However the exact number should be confirmed using a higher resolution data. Other searches have led to much smaller values or upper limits ($f < 10^{-6}$, Black et al. 1987, Chaffee et al. 1988, Levshakov et al. 1992). Levshakov & Varsshalovich (1985) suggested that H$_2$ molecules could be present in the DLA system toward PKS 0528–250. This claim has been confirmed by Foltz et al. (1988) using a 1 Å resolution spectrum. The latter authors derive $N$(H$_2$) = 10$^{18}$ cm$^{-2}$, $b$ = 5 km s$^{-1}$, $T_{ex}$ = 100 K and log $N$(H I) = 21.1±0.3. By fitting the damped absorption together with the Lyman emission from the quasar, Moller & Warren (1993) find log $N$(H I) = 21.35. Three Lyman emission-line objects have been detected within 100h$^{-1}$ kpc from the quasar by Moller & Warren (1993) and confirmed by Warren & Moller (1996) to have redshifts within 200 km s$^{-1}$ from the redshift of the DLA system (z$_{abs}$ = 2.8112 as measured on the Ni II lines by Meyer & York 1987). The widths of the Lyman emission lines are very large (> 600 km s$^{-1}$) and continuum emission could be present (Warren & Moller 1996); this suggests that the gas is not predominantly ionized by the quasar and that star-formation may occur in the clouds, a conclusion reached as well by Ge et al. (1997). The proximity of the quasar makes the case difficult however and careful analysis is needed.

In this paper we use much higher spectral resolution data to reanalyse the molecular lines in this system. We present the observations in Section 2, the results in Section 3 and discuss the low $N$(C I)/$N$(H$_2$) ratio inferred in Section 4.

2. Observations

The observations were carried out at the F/8 Cassegrain focus of the 3.6 m telescope at La Silla, ESO Chile. The spectra were obtained with the ESO echelle spectrograph (CASPEC) and long camera. Three exposures of 5400 s each were obtained under good seeing conditions in November 1995. A 300 line mm$^{-1}$ cross disperser was used in combination with a 31.6 line mm$^{-1}$ echelle grating. The detector was a Tektronix CCD with 1124×1024 pixels of 15 μm square and a read-out noise of 2.5 electrons. For each exposure on the object, flat field images and wavelength comparison Thorium–Argon spectra were recorded. The slit width was 1.6 arcsec corresponding to a spectral resolution of $R$ ∼ 36000 over the wavelength range 3650 – 4850 Å. The spectra were binned in the direction perpendicular to the dispersion axis. The accuracy in the wavelength calibration measured on the calibrated Thorium–Argon spectra is about 0.03 Å.

The data were reduced using the echelle reduction package provided by IRAF. The cosmic-ray events have been removed in the regions between object spectra before extraction of the object. The exposures were co-added to increase the signal to noise ratio. During this merging procedure the cosmic-ray events affecting the object pixels were recognized and eliminated. The background sky spectrum was difficult to extract separately due to the small spacing between the orders in the blue. Instead, we have carefully fitted the zero level to the bottom of the numerous saturated lines in the Ly$\alpha$ forest. The uncertainty on the determination can be estimated to be 5%.

We identify all the absorption features with equivalent widths larger than 5×FWHM×σ where σ is the noise rms in the adjacent continuum. We use the line list to identify the metal line systems in the spectra and more specifically all the absorptions associated with the z$_{abs}$ = 2.8112 DLA system.

3. Results

3.1. Low ionization metal lines

| ION | log N | [Z/H] | Ref |
|-----|------|-------|-----|

1 Moller & Warren 1993; 2 Lu et al. 1996; 3 This work

Lu et al. (1996) have obtained column densities of most of the elements in the DLA system considered here. In addition to the lines identified by Lu et al (1996) we find a possible Ar I doublet from this molecular cloud (see Fig 1). Since our spectrum extends further into the blue, we could also obtain a better estimate of the Fe II column density using the lines from very weak transitions (e.g. Fe II λ1125, Fe IIλ1127, Fe λ11142 etc., see Fig. 1). We also obtained an upper limit to the C I column density which will be useful for constraining the model parameters. The column
densities of different species are given in Table 1. Since in the neutral phase of DLA systems the dominant ionization state of the elements listed in Table 1 is either the neutral (for argon) or the singly ionized (for the others) state, we can estimate element abundances. The values we obtain for the S ii column density is about a factor of two less than that of Lu et al. The reason is that we detect and fit only the strongest component whereas Lu et al. integrate the apparent optical depth from $v = -80$ to 300 km s$^{-1}$. For consistency of the discussion, we adopt the value from Lu et al. Subsequently, since singly ionized species can be found well outside the region where hydrogen is neutral, it must be noticed that the values of the ratios $N(X^{+})/N$(H i) are upper limits.

An interesting limit on the Mg i column density can be obtained from the Lu et al. data. Mg i$\lambda$2026 is blended with Zn i$\lambda$2026. However from Fig. 9 of Lu et al., we can see that the optical depth of the line is smaller than 0.1. If we consider, as for Zn ii and Cr ii that the absorption is spread over 40 km s$^{-1}$ we can infer that $w_{1} < 0.027$ Å. Using the oscillator strength given by Morton(1991), we find $N$(Mg i) $< 6.6 \times 10^{12}$ cm$^{-2}$.

Formation of H$_{2}$ molecules is most efficient in the presence of dust grains (see Section 3.2). In DLA systems the amount of dust is usually estimated from the ratio $N$(Zn ii)/$N$(Cr ii) assuming that, like in the ISM of our galaxy, Zn is not heavily depleted onto dust grains whereas Cr is depleted (Meyer et al. 1989; Pettini et al. 1994, 1997; Lu et al. 1996). Some controversy has arisen however about the presence of dust in DLA systems. Lu et al. (1996) have argued that nucleosynthesis alone can explain the element abundance ratios observed in DLA systems and that the presence of dust is thus questionable whereas Pettini et al. (1997) have claimed that even though nucleosynthesis history of the gas must play a role, the consistent depletion levels of the refractory elements indicates the presence of dust. We discuss the abundance ratios of Table 1 considering the two possibilities in turn.

It is known that Zn and S are not heavily depleted into dust grains (Sembach & Savage 1996) and should reflect the gas-phase abundances which is thus of the order of 0.1–0.2 $Z_{\odot}$. The average value of [Cr/Zn] in the diffuse interstellar clouds with molecular fraction $f$(H$_{2}$) between −6 and −4 is $-1.18 \pm 0.53$ (Roth & Blades 1995). The observed [Cr/Zn] $= -0.47$ in the $z = 2.8112$ system suggests that about 70% of Cr is depleted onto dust grains in the damped system compared to 99% in the diffuse interstellar medium of our galaxy. The observed Ni ii/Cr ii in the 2.8112 system is consistent with the ratio in the interstellar medium. Silicon has the same gas-phase abundance as zinc (see Table 1) which is consistent with the much lower depletion of silicon as compared to iron, chromium and nickel in the interstellar medium. The non detection of Mg i is intriguing. Although the upper limit on Mg ii is consistent with the other element abundances, some depletion could be needed (see Section 4). All these are consistent with the presence of dust in the system with small departure of the total element abundance ratios from the solar values.

It is interesting to note however that in our galaxy, stars with [Fe/H] $\sim -1$, have [Si/Fe] $\sim [S/Fe] \sim 0.4$ (e.g. François 1987) and [Cr/Fe] $\sim [Ni/Fe] \sim 0$ (Magain 1989, Gratton & Sneden 1991) which is approximately what we observe. Thus the assumption of depletion onto dust grains may be questionable. The upper limit on magnesium is consistent with [Mg/Fe] $\sim 0.4$ (Magain 1989). However a better limit on this element would definitively be very helpful. However if we accept the gas-phase metallicities as the true metallicities, then the observed value [Zn/Fe] $= 0.5$ is not consistent with the value observed in the same stars ([Zn/Fe] $= 0$, Sneden & Crocker 1988).

In the case of the $z_{abs} = 2.8112$ system toward PKS 0528–250, we can investigate further this issue by asking the question whether dust is needed to produce the observed amount of H$_{2}$ molecules (see Section 4).

3.2. H$_{2}$ molecules

The consequence of the spectral resolution being nine times larger than the previous published data can be appreciated by comparing Fig. 2 with Fig. 4 of Foltz et al. (1988). In our data, a large number of molecular lines are left unblended making the determination of the line parameters much reliable.

![Fig. 1. Fit result for few weak heavy element transitions in the $z_{abs} = 2.8112$ damped system](image-url)
We have derived the \( N(H_2) \) and \( b \) values using a Voigt profile fitting code (Khare et al. 1997). The oscillator strengths of different transitions given in Morton & Dinerstein (1976) have been used. Only the clean and unblended lines from each rotational level are fitted. The best fit is obtained with a single component model although a few discrepancies between the fit and the data may argue for a two-component model (see also the comment by Jenkins & Peimbert 1997 about this system). The resulting fit is shown in Fig. 2 for a few transitions. The fit parameters are given in Table 2 where the second, third and fourth columns give the statistical weights of different levels, the column density and the number of lines used in the model respectively. The best value for the velocity dispersion is \( b = 9.1 \) km s\(^{-1}\).

### Table 2. \( H_2 \) column densities and excitation temperatures

| LEVEL | \( \frac{N_J}{g} \) \((10^{16} \text{ cm}^{-2})\) | Number | \( T_{ex} \) (K) | \( J_{ex} \) |
|-------|-----------------|--------|-----------------|
| \( J = 0 \) | 1 | \( 0.965\pm0.330 \) | 4 | .... | .... |
| \( J = 1 \) | 9 | \( 4.110\pm0.009 \) | 7 | 229\pm95 | 0-1 |
| \( J = 2 \) | 5 | \( 0.417\pm0.063 \) | 8 | 208\pm36 | 0-2 |
| \( J = 3 \) | 21 | \( 0.216\pm0.029 \) | 3 | 225\pm08 | 0-3 |
| \( J = 4 \) | 9 | \( \leq0.03 \) | ... | 224\pm09 | 1-3 |

The total column density \( N(H_2) \) in the cloud is \( 6 \times 10^{16} \) cm\(^{-2}\) and the measured fractional \( H_2 \) abundance is \( f = 2 N(H_2)/[2 N(H_2) + N(H\,i)] = 5.4 \times 10^{-5} \). This value is obtained using \( N(H\,i) = 2.2 \times 10^{24} \) cm\(^{-2}\) (Moller & Warren 1993), and assuming that all the neutral hydrogen contributing to the damped Ly \( \alpha \) absorption originates from the same region as \( H_2 \). If this were not the case, \( f \) would be higher. The molecular fraction obtained here is two orders of magnitude less than the values quoted by Foltz et al. (1988). However as noted by the latter authors, the column density is very sensitive to the Doppler parameter and their value should be considered as an upper limit.

In the case of thermal equilibrium, the ratio of column densities of two rotational levels is given by the Boltzman equation,

\[
\frac{N(J)}{N(0)} = \frac{g_J}{g_0} \exp \left[ -\frac{BJ(J + 1)}{kT_{ex}} \right].
\]

where \( g_J \) is the statistical weight of any level \( J \) in the vibrational ground state, \( T_{ex} \) is the excitation temperature and the constant \( B/k \) is \( \approx 85 \) K. The values of \( T_{ex} \) derived for different transitions are given in column 5 of Table 2. Lines from higher "\( J \)" levels (i.e. \( J \geq 4 \)) are weak and we could derive only upper limits to column densities.

It is believed that the \( J = 1 \) level is mostly populated by collisions so the excitation temperature, \( T_{01} \), is roughly equal to the kinetic temperature. As can be seen from Table 2, the excitation temperatures derived for different levels are similar, suggesting that \( T_{ex} \) indeed equals the kinetic temperature which is therefore close to \( \sim 220 \) K in this molecular cloud.

As suggested by Jura (1975) the column density ratio \( N(2)/N(0) \) and \( N(3)/N(1) \) are controlled by the kinetic temperature when \( n(H) > 20 \) and \( n(H) > 300 \) cm\(^{-3}\) respectively. Our limit on the population of the \( J = 4 \) rotational level do not add much constraint on the density. However, Ge & Bechtold (1997) report a new determination \( N(4)/N(0) = 4.5 \times 10^{-3} \) by Songaila & Cowie (1995). This new value implies an excitation temperature \( T_{04} = 224 \) K. The calculations by Nishimura (1968) indicate that all this is consistent with a kinetic temperature of \( T \sim 220 \) K and a density \( n \sim 1000 \) cm\(^{-3}\).

Using the asymptotic approximation given by Jura (1974) for the ratio of the molecular to neutral hydrogen densities, \( n(H_2)/n(H) \), as a function of the optical depth within a molecular cloud, we can derive an estimate of the photo-dissociation rate of molecules, \( I \), due to the incident UV flux,

\[
I = \frac{nR}{\delta} \sqrt{\frac{N}{2f}} \quad (2)
\]

where \( \delta = 4.2 \times 10^5 \), \( n \) is the hydrogen density, \( R \) is the rate of molecule formation onto dust grains; \( N \) is the total
H I column density and <f> is the mean molecular fraction observed through the cloud. If we scale R with the metallicities from the value observed in the ISM, then we can estimate that $R \sim 3 \times 10^{-18} \text{cm}^2\text{s}^{-1}$. This may well be an upper limit since the dust to gas ratio in the damped system is smaller than in the ISM (see Secion 3.1). Using the density and the molecular fraction derived above (i.e., $n \sim 1000 \text{ cm}^{-3}$ and $f \sim 5.4 \times 10^{-5}$) we estimate the photodissociation rate of molecules, $I \sim 3.2 \times 10^{-8} \text{s}^{-1}$, and the photo-absorption rate in the Lyman and Werner bands, $\beta_\nu \sim I/0.11 \sim 3 \times 10^{-7} \text{s}^{-1}$ (Jura 1975). This large value results from the large H I column density albeit small molecular fraction seen in $z_{\text{abs}} = 2.8112$ damped system. We are confident that $f$, $n$ and the metallicities are known within a factor of two.

The estimated value of the photo-absorption rate, $\beta_\nu$, is $3 \times 10^{-7} \text{s}^{-1}$. This value is an order of magnitude higher than the values obtained by Ge & Bechtold (1997). It is also two orders of magnitude higher than the average value for the interstellar radiation field in our galaxy (i.e. $\beta_\nu = 5 \times 10^{-10} \text{s}^{-1}$). The average value for the intergalactic medium radiation field calculated for $J_{\gamma}(912 \text{ Å}) = 1$, is $\beta_\nu = 2 \times 10^{-12} \text{s}^{-1}$. Thus the radiation field in the $z = 2.8112$ absorbing cloud is not dominated by the intergalactic UV radiation field. The most probable sources are either the radiation from the quasar or from the young stars in the molecular cloud itself.

If we take quasar alone (see however Section 4) to be the ionizing source then, using $m_\text{B} = 18.17$, $q_0 = 0.5$, $H_\circ = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, the optical to UV spectral index $\alpha = -1 (f_\nu \propto \nu^{-\alpha})$ and the upper limit on $\beta_\nu$, we estimate that the H$_2$ cloud should be at a distance larger than 10 kpc from the quasar.

If we assume that the H$_2$ lines are thermally broadened then the velocity dispersion of 9 km s$^{-1}$ gives a kinetic temperature of $\sim 2000$ K. This is higher than the kinetic temperature inferred from the excitation temperatures. Thus it is possible that there are more than one component in the H$_2$ absorption. This may introduce a small error in the total H$_2$ column density. However the lines are not heavily saturated and hence the errors cannot be large.

3.3. CO molecules

In the galactic diffuse clouds, $N(\text{CO}) \sim 10^{-7} \times N(\text{H})$. As the high redshift DLA systems have, on average, one tenth of the solar metallicity we would expect the $N(\text{CO})/N(\text{H})$ ratio to be lower than $10^{-7}$. Indeed optical and radio searches (e.g. Levshakov et al. 1989; Wilkind & Combes 1994 and references therein) fail to detect CO both in emission and absorption in high $z$ damped absorbers.

However CO emission is detected from a few high redshift quasars and ultra-luminous infrared galaxies (see e.g. Barvainis et al. 1994, Ohta et al. 1996; Omont et al. 1996; Guilloteau et al. 1997). These detections suggest that a large amount of mass in host galaxies (or surrounding regions) of some of the high redshift AGNs is in the form of molecules.

We have searched for the presence of absorption due to CO A-X molecular bands in a FWHM = 0.6 Å spectrum obtained by Petitjean & Bergeron (1994) primarily for studying intervening C IV systems (see their paper for the observational details). No strong CO absorption is detected from the $z = 2.8112$ system (see Fig. 3).

![Fig. 3. Plot showing the spectrum in the rest wavelength of different A-X bands in CO due the $z_{\text{abs}} = 2.8112$ damped system. The centres of each band is marked with an arrow.](image-url)
the \(N(\text{CO})/N(\text{H}_2)\) ratios seen in the diffuse interstellar medium. They also noted that \(N(\text{C} \\text{ i})\) is, on average, 10 times larger than \(N(\text{CO})\). If \(N(\text{C} \ \text{ i})\) is greater than \(N(\text{CO})\) in the system under consideration also, then the upper limit on \(N(\text{C} \ \text{ i})\) suggests that the value of \(N(\text{CO})\) should be an order of magnitude less than the derived upper limit.

4. The low \(N(\text{C} \ \text{ i})/N(\text{H}_2)\) ratio

The ratios \(N(\text{C} \ \text{ i})/N(\text{H} \ \text{ i}) < 2.2 \times 10^{-9}\) and \(N(\text{H}_2)/N(\text{H} \ \text{ i}) = 2.7 \times 10^{-5}\) derived from this study are surprisingly low. Indeed in the interstellar medium of our Galaxy, all the clouds with log \(N(\text{H} \ \text{ i}) > 21\) have log \(N(\text{H}_2) > 19\) and log \(N(\text{C} \ \text{ i}) > 14\) (Jenkins & Shaya 1979). It thus may be interesting to investigate the reasons for such low ratios.

Formation of \(\text{H}_2\) is expected on the surface of dust grains if the gas is cool, dense and mostly neutral, and from the formation of negative hydrogen if the gas is warm and dust free (see e.g. Jenkins & Peimbert 1997). Given the neutral hydrogen column density of this system and the evidence for depletion onto dust grains (see however Warren & Möller 1996), the first process should dominate. Destruction is mainly due to UV photons. The effective photodissociation of \(\text{H}_2\) takes place in the energy range 11.1–13.6 eV, through Lyman-Werner band line absorption. Since the ionization potential of C \text{ i} is 11.2 eV, it is sensitive to the same photo-ionization field as \(\text{H}_2\) in the neutral phase. If the \(\text{H}_2\) lines are saturated then the cloud is self-shielded against further photodissociation of \(\text{H}_2\). In this case however large values of \(N(\text{H}_2)\) to \(N(\text{C} \ \text{ i})\) ratio are easily produced.

We run grids of photoionization models using CLOUDY (Ferland 1993). These models take into account photo-dissociation of \(\text{H}_2\) molecules using the approximations outlined by Tielens and Hollenbach (1985). The incident radiation field is averaged over the wavelength interval 912–1109 Å and is redistributed according to the interstellar radiation spectrum given by Habing (1968).

In our calculations we take the gas phase abundances to be 1/10 of solar. The grain composition is assumed to be similar to that of the Galactic ISM and we use the dust to gas ratio as a free parameter. We perform the photoionization calculations for different ionizing radiation spectra and a range of ionizing parameters, \(U\).

We consider four possible spectral energy distribution for the incident radiation field which are (1) a simple power–law of index \(\alpha\), \(F(\nu) \propto \nu^{-\alpha}\); (2) a power-law with a "big bump" modeled as a black-body of temperature 50 000 K, the relative contributions of the power-law spectrum and the black-body is characterized by the index \(\alpha_{\text{ox}} = \log F(2500 \ \text{Å})/F(2 \text{ keV})\); (3) a typical spectrum of AGNs (Mathews & Ferland 1987); and (4) a starburst (Charlot, private communication). The optical to X-ray spectral energy distribution of PKS 0528–250 is not well defined. Wilkes et al. (1994) failed to detect X-ray emission from this quasar in their Einstein IPC data. They

![Fig. 4. H2 and C i column densities versus ionization parameter for different ionizing spectra (the SEDs are given in Fig. [1]). The cloud is modeled as a slab of constant density \(n = 100 \ \text{cm}^{-3}\) illuminated on one side by an incident flux, resulting in an ionization parameter \(U\) (ratio of the density of ionizing photons to the density of hydrogen). Metallicity is a tenth of solar and the amount of dust is taken as a fraction of the ISM dust content.](image-url)
derive an upper limit on $\alpha_{\text{ox}}$ of $-1.34$. It is known that a typical quasar will have $\alpha_{\text{ox}}$ in the range $-1.0$ to $-2.0$ with a mean of $-1.5$ (e.g. Wilkes et al. 1994). Thus in our model we use either $\alpha_{\text{ox}} = -1.5$ or $-2.0$.

The predicted column densities of H$_2$ and C i as a function of the ionizing parameter $U$ for different models are given in Fig. 3 (the SEDs are shown for direct comparison in Fig. 3). For all models, log $N$(H i) = 21.35 and $n_H = 100$ cm$^{-3}$. We have checked that the exact value of $n_H$ has little effect on the results.

To reproduce the small $N$(C i)/$N$(H i) ratio, the spectrum must be steep to favor ionization of C i. This is why a power-law spectrum with $\alpha = -2$, a "big-bump" spectrum with $\alpha_{\text{ox}} = -2$ and the starburst spectrum can reproduce the ratio with somewhat different ionizing parameters. The "big-bump" spectrum is favored because the X-ray tail maintains the temperature of the neutral gas above 100 K. The other models imply too low a temperature compared to what we derived from the H$_2$ features. However all the models fail to reproduce at the same time the H$_2$ column density. It is apparent from the figure that steeper spectra could meet the constraints. However again the temperature would be too low. Moreover, all the models predict log $N$(Mg i) > 13.5. This is a factor of seven larger than the upper limit we derived from the Lu et al. (1996) data. In the framework of these models, the only solution we can find is to decrease the abundances of carbon by a factor of two and that of magnesium by a factor of seven. This could reflect true relative abundances or depletion onto dust grains.

Dust is needed to explain the H$_2$ column density as is apparent from Fig. 3. The H$^-$ process is more efficient than the dust process at temperature $T > 500$ K and when $n_e$ is not negligible, thus in the partially ionized region. However the very large H i column density of this damped Ly$\alpha$ system requires most of the gas to be neutral where this process is negligible because of the low temperature resulting from the steep spectrum needed to explain the lack of C i and Mg i.

5. Conclusion

By fitting the different H$_2$ transitions that we detect in a high resolution spectrum of PKS 0528–250, we derive log $N$(H$_2$) $\sim$ 16.78 and $T_{\text{ex}}$ $\sim$ 200 K that is most certainly the true kinetic temperature of the gas. For this temperature, the relative populations of rotational levels 0 to 4 indicate that the density is of the order of 1000 cm$^{-3}$. Therefore the dimension of the neutral cloud along the line of sight is less than 1 pc. It must be noticed that the damped absorber must cover the broad line region. Indeed there is no residual flux in the bottom of the Ly$\alpha$ absorption line which completely absorbs the Ly$\alpha$ emission from the quasar over more than 5000 km s$^{-1}$ (Møller & Warren 1993). Since the dimension of the BLR in QSOs can be approximated as $R \sim 0.3 L_{46}^{0.5}$ where $L_{46}$ is the bolometric luminosity in units of $10^{46}$ erg s$^{-1}$ (Collin, private communication). The radius of the BLR in PKS 0528–250 is thus of the order of 10 pc. The transverse dimension of the damped cloud must be thus larger than 10 pc and the cloud must be quite flat.

We can derive an upper limit on the transverse dimension of the cloud by interpreting the non-detection of redshifted 21 cm absorption (Carilli et al. 1996) as an effect of partial covering factor of the continuum radio emission by the cloud. Indeed the size of the radio source is 1 arcsec or $5h_{75}^{-1}$ kpc. If the spin temperature is equal to the kinetic temperature we derived in sect. 3.2, this implies that the covering factor should be less than 0.3 and thus the radius of the cloud along the transverse direction is less than 1 kpc.

We determine upper limits for the C i, Mg i and CO column densities (log $N$(C i) < 12.7, log $N$(Mg i) < 12.8 and log $N$(CO) < 13.2). Based on simple photoionization models we conclude that (i) no simple model can reproduce at the same time the low $N$(C i)/$N$(H i), $N$(Mg i)/$N$(H i) ratios and the presence of molecules at the level observed; (ii) steep spectra are required to reproduce the low $N$(C i)/$N$(H i) and $N$(Mg i)/$N$(H i) ratios but they predict temperatures smaller than 100 K in conflict with the excitation temperature derived from the
$H_2$ transitions; (iii) the only way to keep the temperature as high as 200 K is to allow for some X-ray flux heating the gas; (iv) in the framework of these models, dust is needed to produce the observed amount of molecules; (v) the gas phase abundances of carbon and especially magnesium should be smaller than 0.1 of solar.

In view of the models we explored, the most likely ionizing spectrum is a composite of a UV-"big bump" possibly produced by a local starburst and a power-law spectrum from the QSO that provides the X-rays.

Acknowledgements. We thank Drs. L. Cowie and J. Bechtold for useful information, Stéphane Charlot for providing us with the new models of starburst SED and an anonymous referee for insightful comments.
