Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
COVID-19 and metabolic disease: mechanisms and clinical management

Charlotte Steenblock, Peter E H Schwarz, Barbara Ludwig, Andreas Linkermann, Paul Zimmet, Konstantin Kulebyakin, Vsevolod A Tkachuk, Alexander G Markov, Hendrik Lehnter, Martin Hrabé de Angelis, Hannes Rietzsch, Roman N Rodionov, Kamillesh Khunti, David Hopkins, Andreas L Birkenfeld, Bernhard Boehm, Richard M G Holt, Jay S Skylar, J Hans DeVries, Eric Renard, Robert H Eckel, K George M M Alberti, Bruno Gelenze, Juliana C Chan, Jean Claude Mbanya, Henry C Onyegbutulem, Ambady Ramachandran, Abdul Basit, Mohamed Hassanein, Gavin Bewick, Giatgen A Spinas, Felix Beuschlein, Rüdiger Landgraf, Francesco Rubino, Galtrude Mingrone, Stefan R Bornstein

Up to 50% of the people who have died from COVID-19 had metabolic and vascular disorders. Notably, there are many direct links between COVID-19 and the metabolic and endocrine systems. Thus, not only are patients with metabolic dysfunction (eg, obesity, hypertension, non-alcoholic fatty liver disease, and diabetes) at an increased risk of developing severe COVID-19 but also infection with SARS-CoV-2 might lead to new-onset diabetes or aggravation of pre-existing metabolic disorders. In this Review, we provide an update on the mechanisms of how metabolic and endocrine disorders might predispose patients to develop severe COVID-19. Additionally, we update the practical recommendations and management of patients with COVID-19 and post-pandemic. Furthermore, we summarise new treatment options for patients with both COVID-19 and diabetes, and highlight current challenges in clinical management.

Introduction

Although many people with SARS-CoV-2 infection show no or mild symptoms, the resulting systemic disease, COVID-19, has various presentations, including severe illness and fatal outcomes.

Around a fifth of the global population is affected by one or more chronic conditions, putting them at increased risk of severe COVID-19 (defined as fever and at least one sign or symptom of respiratory disease and requirement for hospitalisation), if infected with SARS-CoV-2.1 Underlying conditions were reported in more than 50% of patients with COVID-19 and around a third of patients had multiple comorbidities.2 Age and comorbidities that are common in older people (eg, ≥65 years), such as obesity, diabetes, hypertension, and pulmonary, cardiovascular, kidney, and non-alcoholic fatty liver disease, influence the progression and prognosis of COVID-19.3–8 Additionally, COVID-19 in conjunction with type 2 diabetes and obesity, which are both characterised by severe insulin resistance,9 has numerous consequences. BMI is strongly correlated with severe manifestations of COVID-19 from critical pneumonia that is not driven by SARS-CoV-2,10 and the presence of obesity might shift COVID-19 towards severe manifestations of COVID-19 to younger age groups (aged <50 years), as reported by researchers at Johns Hopkins.11 Additionally, underlying diseases might be aggravated, increasing the susceptibility of patients to serious long-term consequences.12–14 The severity and mortality of COVID-19 associated with these medical conditions showed considerable geographical differences.15 Deprived populations with scarce access to health services in normal circumstances are most vulnerable during times of crisis.16 Furthermore, in some low-income and middle-income countries, a high socioeconomic status is sometimes associated with obesity; whereas, in high-income countries, the inverse is often the case.17 In countries with a low prevalence of obesity, the fatality rates from COVID-19 have been lower than in countries with a high prevalence of obesity, although potential confounders should be taken into account.18

Now, more than 1·5 years after the initial outbreak of SARS-CoV-2, there is strong evidence that people with metabolic diseases are not only more susceptible to severe COVID-19, but also have an increased risk of post-acute sequelae of COVID-19 and vaccine breakthrough.19–23

Metabolic and endocrine pathways linked to SARS-CoV-2

Entry of SARS-CoV-2 into cells is mediated via binding of viral spike glycoproteins to cellular angiotensin-converting enzyme (ACE) 2. In the renin–angiotensin–aldosterone system (RAAS), ACE2 acts as key regulator, controlling the generation of the vasodilating angiotensin 1–7 from angiotensin II. Furthermore, ACE2 is able to cleave angiotensin I to angiotensin 1–9, which can be further converted to angiotensin 1–7 by ACE. ACE2, angiotensin 1–7, and its Mas receptor constitute the vasoprotective arm of the RAAS, leading to anti-inflammatory and antifibrotic responses (figure 1A).24 However, when ACE activity is high and ACE2 is inhibited, angiotensin II acts via the angiotensin II receptors, AT1R and AT2R, to exert proinflammatory responses and to stimulate aldosterone production. Therefore, deregulation of the ACE or ACE2 balance can lead to arterial hypertension accompanied by an exaggerated inflammatory response, which, in the absence of adequate intervention, might culminate in end-organ damage.25

Cellular concentrations of ACE2 depend on several factors, such as other RAAS components, gene polymorphisms, and clinical conditions (eg, hypertension and vascular diseases).26 ACE2 is expressed in many tissues
and cell types; therefore, at the onset of the pandemic, high ACE2 expression was speculated to be partly responsible for infection with SARS-CoV-2. In the endocrine system, ACE2 is expressed in all organs of the hypothalamus–pituitary–adrenal cortex (HPA) axis; however, contradicting results have been presented in pancreatic islets. Some reports show no expression of ACE2 in the islets of Langerhans but in pancreatic epithelial cells only, whereas other studies in patients without COVID-19 have shown expression of ACE2 in β cells. A sub-group of authors of this Review previously investigated expression of ACE2 and SARS-CoV-2 infection of β cells in 11 patients who died due to COVID-19. Compared with other study cohorts of just one to three patients, we observed that only around 30% of the patients expressed ACE2 in β cells, indicating that other factors were also involved in the infection. Whether the expression of ACE2 observed in some patients with COVID-19 was due to the infection itself or, conversely, that these patients were infected due to the high expression of ACE2, remains uncertain. Expression of ACE2 is increased following inflammatory stress, which suggests enhanced β-cell sensitivity to SARS-CoV-2 during inflammatory conditions.

Following binding of SARS-CoV-2 to ACE2, the receptor is internalised by the infected cell, leading to a distinct downregulation of ACE2. This downregulation of ACE2 in the intestinal epithelium has been suggested to lead to upregulation of SGLT1, thereby precipitating hyperglycaemia. Furthermore, the protective arm of the RAAS is potentially removed, which might lead to a multiorgan hyperinflammatory response (ie, cytokine storm). Thus, the RAAS and, in particular, ACE2 seem to offer attractive therapeutic targets against COVID-19. Although medications, such as ACE inhibitors and angiotensin II receptor blockers, could increase ACE2 expression and potentiate SARS-CoV-2 cell entry, increased ACE2 production would result in a higher circulating concentration of soluble ACE2, which would potentially neutralise SARS-CoV-2 (table 1). Use of ACE inhibitors or angiotensin II receptor blockers has been reported to be higher in patients with COVID-19 than in patients without, which is caused by the higher prevalence of COVID-19 among people with hypertension, cardiovascular, and renal diseases. Nevertheless, to the best of our knowledge, none of the observational studies performed to date has shown an association between the use of ACE inhibitors or angiotensin II receptor blockers and disease outcome, severity, or death. Significant and independent associations between plasmatic aldosterone and C-reactive protein concentrations and the severity of COVID-19 have been reported.

SARS-CoV-2 spike proteins require two proteolytic processing steps before cell entry. These steps are mediated by host-cell proteases, such as furin, TMPRSS2, and cathepsin L, leading to fusion of the viral envelope and the plasma or endosome membrane of the host cell (figure 1B).

At the time of writing, a number of new variants of the original SARS-CoV-2 strain have emerged, which are up to 90% more contagious. The alpha (B.1.1.7), beta (B.1.351), and gamma (P.1) variants are mutated in the SARS-CoV-2 spike proteins required for infection with SARS-CoV-2. Expression of ACE2 is regulated by the binding affinity to ACE2 which is mediated by host-cell proteases, such as furin, TMPRSS2, and cathepsin L, leading to fusion of the viral envelope and the plasma or endosome membrane of the host cell (figure 1B).
affinity for ACE2 than do other variants, and shows increased transmissibility.18 Thus, blocking the interaction between ACE2 and the receptor binding domain could be a potential approach to inhibit transmission of and infection with SARS-CoV-2,13 and the SARS-CoV-2 receptor binding domain could serve as a central target for conceiving therapeutic strategies against COVID-19.19

Additional factors expressed in pancreatic β cells have been identified as crucial for infection with SARS-CoV-2 (figure 1B).29,30 NRP1, known to bind furin-cleaved substrates, facilitates SARS-CoV-2 entry and infection,60 suggesting that virus entry is increased in cells with a low expression of ACE2 due to promotion of the interaction between SARS-CoV-2 and ACE2 via NRP1. In addition, HMGB1, a DNA-binding protein that regulates chromatin and is known to be proviral, was shown to regulate the expression of ACE2 and be essential for viral entry.61 Furthermore, HMGB1 is released from necrotic cells, and systemic concentrations of TNFα and INFγ were shown to cause necrosis in individuals with SARS-CoV-2 infection.62 Along similar lines, the key kinase mediator of necroptosis, RIPK3, is strongly upregulated in patients with severe COVID-19,63 indicating a feed-forward loop of cell death and inflammation.64 Alongside HMGB1, members of the switching defective–sucrose nonfermenting chromatin-remodelling complex, such as SMARCA4, regulate the expression of ACE2 (figure 1B).65 These alternative factors are potential new therapeutic targets for inhibiting SARS-CoV-2 infection.

The MERS-CoV receptor, DPP-4, has also been suggested as an alternative receptor for SARS-CoV-2.66 DPP-4 has been shown to be expressed by cells of the immune system, on epithelial and endothelial cells in the pancreas, lung, and kidney,67 and in both the exocrine and endocrine pancreas.68 DPP-4 is an aminopeptidase with an important role in glucose metabolism, and DPP-4 inhibitors are widely used for the treatment of type 2 diabetes.69 First reports did not show any clinical evidence to suggest that drugs targeting pathways related to DPP-4 exhibit any benefits or harm in relation to human coronavirus infections.69 However, a study with 2.8 million people showed worse COVID-19 outcomes in patients with diabetes receiving DPP-4 inhibitors than in those who had not received such treatment, although this finding was probably due to confounding by indication.70 Reports have since suggested improved clinical outcomes and a reduced risk of mortality in patients with COVID-19 and diabetes receiving DPP-4 inhibitor therapy (table 1).71,72 These contradictory results from observational studies emphasise the importance of well designed randomised, double-blind, placebo-controlled clinical trials to ascertain a potential benefit.

**Table 1: Glucose-lowering medications with potential interfering effects on COVID-19**

| Potential positive effects | Potential negative effects |
|----------------------------|----------------------------|
| Glucocorticoids22,41 Anti-inflammatory effects | Risk of hyperglycaemia |
| ACE inhibitors and angiotensin II receptor blockers22,41,42 | Increases expression of soluble ACE2, neutralises virus |
| Metformin22,43 | Stabilises ACE2; modulates ACE2–angiotensin II–AT1R axis; inhibits host-virus binding; inhibits mitochondrial complex I; protects endothelium and vasculature; decreases virus maturation |
| SGLT2 inhibitors21,44 | Reduces viral load, positive effects on cardiovascular and renal functions |
| GLP-1 receptor agonists21,45,46 | Anti-inflammatory effects; improves endothelial dysfunction; improves cardiovascular and renal functions |
| DPP-4 inhibitors21,45,46 | Blocks virus uptake; reduces inflammatory response; well tolerated |
| Insulin21,45,46 | Anti-inflammatory effects |
| Glucocorticoids22,41 | Anti-inflammatory effects |
| ACE inhibitors and angiotensin II receptor blockers22,41,42 | Increases expression of membrane-bound ACE2 might increase virus entry (no clinical evidence) |
| Metformin22,43 | Risk of dehydration, lactic acidosis, chronic kidney disease, and acute kidney injury |
| SGLT2 inhibitors21,44 | Risk of dehydration, diabetic ketoacidosis, and acute kidney injury |
| GLP-1 receptor agonists21,45,46 | Reduces appetite and increases satiety, gastrointestinal symptoms |
| DPP-4 inhibitors21,45,46 | Increases mortality in older patients (likely due to confounding by indication) |
| Insulin21,45,46 | Hypoglycaemia; high doses increase COVID-19 mortality |

Of note, many of these results are retrospective and confounded by indications, patients’ risk profiles, or severity of diseases. ACE-angiotensin-converting enzyme.

Predisposition to severe COVID-19 outcomes in patients with metabolic and endocrine diseases

Excess adiposity is a risk factor for severe COVID-19 and mortality though a number of mechanisms, including increased inflammation, hypercoagulability, and mechanical obstruction.44 One explanation for the predisposition to poor outcomes in patients with severe COVID-19 and obesity might be the physical stress on ventilation through obstruction of diaphragm excursion. Furthermore, diabetes and obesity are associated with an increased risk of pulmonary fibrosis, chronic obstructive pulmonary disorder, and reduced respiratory function.70 Obesity, diabetes, and hypertension increase the risk of stroke and cardiovascular complications,71 risk factors that are also observed in patients with severe COVID-19 (figure 2). These patients exhibit an exacerbated coagulation response due to overexpression of prothrombotic factors, such as coagulation factors (II, VII, VIII, IX, XI, and XII), PAI-1, and von Willebrand factor, which, in combination with pre-existing conditions, could increase the probability of stroke or pulmonary embolism.72,73
Metabolic dysfunction might lead to a baseline state of chronic inflammation, given that proinflammatory cytokines, such as TNFα, IL-6, and IL-1β, are upregulated in the adipose tissue of patients with metabolic syndrome. These cytokines inhibit insulin signalling. In turn, cytokine upregulation results in paracrine and endocrine effects, which lead to an increase in leptin and PAI-1, and a reduced release of adiponectin. Thus, metabolic organs, such as white adipose tissue, skeletal muscle, the liver, and the pancreas, are infiltrated with macrophages and other immune cells (figure 2). In diabetes, insulin resistance leads to an increased infiltration of macrophages into adipose tissue, especially M1 macrophages. Obesity is also associated with a high baseline expression of the IL-6 receptor. Compared with individuals without overweight, the expression of the IL-6 receptor in individuals with obesity is not downregulated by an increased cytokine concentration, therefore leading to a constant low-grade inflammatory state, termed metaflammation. Dysfunction in insulin signalling further contributes to chronic inflammation via activation of AP-1 and NFκB, leading to a decrease in anti-inflammatory cytokines and an increase in TNFα, IL-6, and IL-1β. This shift from a predominantly anti-inflammatory profile to a pro-inflammatory profile enhances insulin resistance.

Type 2 diabetes is a progressive disease due to insulin resistance, together with chronic inflammation and endothelial and β-cell dysfunction. In severe COVID-19, the inflammatory response to SARS-CoV-2 infection can worsen insulin resistance and endothelial dysfunction (figure 2). Synergy between COVID-19 and type 2 diabetes and obesity might further amplify the inflammatory response and downregulate interferon responses, contributing to increased disease severity in patients with diabetes and obesity. Dysregulation of the RAAS and downregulation of ACE2 expression, in conjunction with stress signalling, can increase insulin resistance. Thus, insulin resistance, by triggering airway hyper-reactivity, increases the risk of respiratory failure and cardio-pulmonary collapse in patients with diabetes and COVID-19.

Besides their role in the immune response against viral infections, cytokines activate the HPA axis, resulting in the release of adrenal glucocorticoids. In turn, glucocorticoids produce negative feedback on immune cells to suppress further synthesis and release of cytokines. Thereby, the host receive a partially protective signal against the destructive consequences of an overactive immune response, such as tissue damage, autoimmunity, or septic shock. Such effects have been clinically reported during dexamethasone administration, which, at the time of writing, is the most effective treatment for patients with severe COVID-19 with pulmonary involvement. Furthermore, inhaled glucocorticoids (eg, budesonide) have been shown to reduce the time to partial recovery after early COVID-19. These findings have led to the widespread use of glucocorticoids to treat patients with not only moderate-to-severe but also, frequently, mild forms of COVID-19 (table 1).

Diseases of the HPA axis are per se not expected to increase the risk of severe COVID-19. However, hormonal replacement therapies or immunosuppression might increase the possibility of an undesirable outcome. Thus, patients with primary or secondary adrenal insufficiency are at increased risk of poor prognosis if the glucocorticoid replacement therapy is not adequately controlled.

A prospective study in patients with renal disease showed that full vaccination with the mRNA-1273 vaccine (Moderna) induced a seroconversion rate of 95% in patients on dialysis, whereas this rate was markedly impaired in recipients of kidney transplants (42%). Seroconversion rates were lower in both of these patient subgroups vaccinated with the BNT162b2 mRNA vaccine (Pfizer–BioNTech). Furthermore, immunosuppressive drug number and type were major determinants of seroconversion failure in patients on dialysis and in transplant recipients, suggesting immune monitoring and adaption of vaccination protocols for these patients.

**Effects of SARS-CoV-2 on the metabolic and endocrine systems**

Following infection with SARS-CoV-2, toll-like receptors 2, 3, and 4 are activated, and IL-1β and IL-6 are released. The metaflammation observed in patients with metabolic disorders allows for a hyperimmune response, which reaches pathogenic levels. This cytokine release provokes fever, systemic inflammation, and subsequent sepsis.

---

**Figure 2: Clinical manifestations and complications of diabetes or obesity and COVID-19**

In the white adipose tissue of individuals with obesity, adipocytes are hypertrophic and the tissue is infiltrated with proinflammatory immune cells that secrete cytokines, chemokines, and adipokines, leading to a permanent inflammatory phenotype. In diabetes, insulin resistance also leads to an increased infiltration of M1 macrophages into adipose tissue. Following infection with SARS-CoV-2, this chronic inflammation might aggravate COVID-19 symptoms in a synergy effect, resulting in metaflammation and a cytokine storm, which contribute to severe COVID-19.
In terms of the pathophysiology, endocrine and metabolic organs (including the brain, pancreas, liver, skeletal muscle, and adipose tissue) might be damaged either directly or indirectly by viral infection and contribute to the development of new-onset hyperglycaemia or insulin resistance in survivors of COVID-19. Based on experiments in islets isolated from human donors and infected with SARS-CoV-2, and on data from post-mortem tissue from patients who died due to COVID-19, SARS-CoV-2 can infect and replicate in cells of the endocrine and exocrine pancreas.28 Furthermore, infiltration with immune cells and signs of necroptosis in the exocrine and endocrine pancreata have been observed in patients with COVID-19.34 These findings could imply that β-cell infection with SARS-CoV-2 might lead to either direct or indirect impairment of β-cell function, causing variable degrees of metabolic dysregulation.

New-onset hyperglycaemia, ketoacidosis, diabetes, and severe metabolic complications of pre-existing diabetes have been frequently observed in patients with COVID-19.46–60 Data from the German Diabetes Prospective Follow-up Registry, a nationwide registry with a coverage of more than 90% of paediatric patients with type 1 diabetes, have shown a significant increase in diabetes diagnostic during the COVID-19 pandemic, especially in children younger than 6 years.59 Of note, indirect effects, such as changes in parental behaviour and health-care accessibility, might have also had an influence on the increase in prevalence of new-onset type 1 diabetes in children.45 Nevertheless, evidence is accumulating suggesting COVID-19 as a cause or trigger of new-onset diabetes.69 Observations of pancreatitis following COVID-19 have also been reported.68 Nonetheless, whether COVID-19 can directly or indirectly lead to new-onset diabetes or accelerate pre-existing unrecognised diabetes or prediabetes remains a subject of discussion.64 As such, this notion is currently being examined in a global registry, CoviDiab.62 Furthermore, a group of international software developers, data scientists, and health professionals have built a non-for-profit graph database, CovidGraph, to make all information related to COVID-19 searchable and accessible in one database.

Implications for medications and therapy

Diabetes and obesity are among the main risk factors associated with morbidity in patients with COVID-19. Reducing the risk factors associated with COVID-19 morbidity could be a reasonable goal for public health (panel). Apart from medical considerations, patients with chronic conditions have been especially vulnerable throughout the pandemic due to reduced access to medical care and personal insecurity due to quarantine measures. In many places around the world, access to diabetes care has been reduced, and patients have been reluctant to access on-site medical care because of fear of exposure to SARS-CoV-2 infection on medical premises. A global survey of health-care professionals reported that management of diabetes and hypertension was often disrupted during the pandemic.65 Additional complications have also resulted from considerable reductions in physical activity, changes in eating habits, and associated-weight gain. Overall, physical activity was lower in adults with type 2 diabetes during lockdown restrictions, particularly in women, older people, individuals with obesity, and minority ethnic populations.66 Despite the expected negative impact of lockdown, retrospective analyses have not reported a worsening of glucose control due to lifestyle changes.67

By contrast, it is evident that an endemic increase in excess weight and obesity in the global population, suggested to have caused more than a doubling of the number of people with type 2 diabetes over the past two decades, has now contributed to an excess of deaths due to COVID-19.68 Therefore, there is an urgent need for expert advocacy in societal changes for the prevention of type 2 diabetes and obesity, directed at improving the diet and lifestyle of populations. Individually targeted, evidence-based health promotion, weight management, behavioural change, and psychosocial support services need vigorous support from diabetologists and other health professionals on the front-line.69

An increase in perceived stress has been shown to be associated with reduced glycaemic control and increased risk of COVID-19.70–72 Strategies to avoid physical inactivity and reduce stress levels can promote cardiovascular protection, and have to be considered during the pandemic. Promotion of physical activity is prioritised by public health agencies and has been incorporated into routine medical care (panel). A home-based training protocol could be an important and effective strategy for individuals who need to remain safe and physically active at home.73 The interlinked pathological mechanisms between metabolic diseases and COVID-19 create the pathophysiological basis for how to treat diabetes and control dysglycaemia. Managing patients with type 2 diabetes should always include a component of reducing or eliminating insulin resistance in these patients, as well as reducing hyperglycaemia (panel).

In the past 18 months, we have gained substantial insights into the association of glucose-lowering therapies and drug classes, and their association with mortality related to COVID-19 (table 2).74,75 These findings indicated that there is no reason to cease antidiabetic or hypertensive medication during the pandemic. However, as most studies were observational, performed retrospectively, and might have been affected by confounding by indication, well designed clinical studies are urgently needed. Until now, DARE-19 is the only published, randomised, double-blind, placebo-controlled trial of a glucose-lowering agent in patients hospitalised with COVID-19 with at least one cardiometabolic risk factor.76 This trial, which excluded...
critically ill patients, suggested that the SGLT2 inhibitor, dapagliflozin, was safe and well tolerated, but did not result in a significant risk reduction in organ dysfunction or death, nor in an improvement in clinical recovery.40–42 Another observational study investigating SGLT2 inhibitors in patients with type 2 diabetes and COVID-19 was associated with an 18% reduction in mortality.77 However, this finding was probably due to confounding by indication, given the reduced use of this drug class in older people, particularly those with renal insufficiency and frailty. Caution should be taken when using these drugs because they require hydration and appropriateness of insulin doses to prevent euglycaemic or hyperglycaemic ketoacidosis (table 1). In addition to the findings that dapagliflozin had no negative effect on predisposition to SARS-CoV-2 infection or aggravation of the disease course, there have been suggestions that DPP-4 inhibitors and metformin might or aggravation of the disease course, there have been suggestions that DPP-4 inhibitors and metformin might

In this cohort, α-glucosidase inhibitors were associated with a 26% increase in COVID-19 mortality; however, the number of deaths related to COVID-19 was too small to evaluate. Use of α-glucosidase inhibitors should be carefully considered.48 Metformin seems to be an effective therapy with pleiotropic effects for patients in acute, chronic, and even recovery phases of COVID-19.114–116 However, some observational studies have shown a marked increase of lactic acidosis in hospitalised patients with diabetes and COVID-19 on metformin, albeit without an effect on mortality. However, this result was probably due to confounding by indication since DPP-4 inhibitors are more likely to be used in older people and in patients with kidney disease and frailty. This study, which was a large, nationally representative, population-based observational study of 2.85 million people with type 2 diabetes also presented statistical evidence that patients who were prescribed metformin, SGLT2 inhibitors, and sulfonylureas had a lower mortality risk than did patients who did not use these medications.49 In this cohort, α-glucosidase inhibitors were associated with a 26% increase in COVID-19 mortality; however, the number of deaths related to COVID-19 was too small to evaluate. Use of α-glucosidase inhibitors should be carefully considered.48

Metformin seems to be an effective therapy with pleiotropic effects for patients in acute, chronic, and even recovery phases of COVID-19.114–116 However, some observational studies have shown a marked increase of lactic acidosis in hospitalised patients with diabetes and COVID-19 on metformin, albeit without an effect on mortality.49

The continued use of sulfonylurea might be justified in stable patients with COVID-19 who are not at risk of hypoglycaemia and have regular meals in an ambulatory setting.7 GLP-1 receptor agonists appear to be neutral to COVID-19 mortality and should be carefully evaluated in severely ill patients with COVID-19, considering their anorexic effects. However, their potential benefits should also be balanced, given that these drugs have anti-inflammatory actions and protective effects on the lung, and could be effective against COVID-19.117–119 To reduce cytokine release in patients with moderate-to-severe COVID-19, IL-6 receptor blockade with tocilizumab is used.120 This treatment has been reported to have a positive effect on insulin resistance and insulin sensitivity.121 However, hyperglycaemia has been shown to impair the effectiveness of this medication,122 which further emphasises the importance of glycaemic control in patients with COVID-19.

It is important to differentiate between ongoing diabetes treatment and treatment of hyperglycaemia arising during acute SARS-CoV-2 infection. Currently, there is a strong rationale to maintain recommendations to avoid treatment with metformin or SGLT2 inhibitors in patients with severe COVID-19 to reduce the risk of lactic acidosis or ketoacidosis associated with use of these drugs in the presence of severe infection. In patients with severe COVID-19, intravenous insulin treatment is
Contraindications: Thiazolidinedione; sulfonylurea; α-glucosidase inhibitors

Recommendations according to guidelines:

| No COVID-19 (primary care) | Mild COVID-19 (hospital) | Moderate COVID-19 (intensive care) | Severe COVID-19 (intensive care) |

| Metformin; GLP-1 receptor agonists; insulins | DPP-4 inhibitors; SGLT2 inhibitors | DPP-4 inhibitors; GLP-1 receptor agonists; insulins | DPP-4 inhibitors; insulins |

Use caution NA: Thiazolidinedione

Contraindications NA: NA

Thiazolidinedione; sulfonylurea

Table 2: Recommended antidiabetic management of patients with COVID-19

...worsening of insulin action, or both. By contrast, patients with type 2 diabetes and COVID-19 receiving insulin treatment had a worse prognosis, with increased mortality associated with insulin therapy, compared with their counterparts who had not received insulin treatment. This finding is probably explained by confounding with severity of disease, given that insulin treatment is a marker for advanced diabetes. Although insulin treatment in the intensive care unit (ICU) is not debatable, hyperglycaemia in people with diabetes admitted to ICU should be handled by intravenous insulin using exact dosing with a perfusion device. Frequent glucose monitoring is mandatory with use of glucocorticoid and anti-inflammatory drug therapy, and prophylactic anticoagulant therapy should be provided in patients with diabetes and COVID-19. Importantly, the US Food and Drug Administration has issued guidance on an emergent basis to expand the availability and capability of non-invasive, remote monitoring devices for patients with diabetes during the COVID-19 pandemic. This change was made in an effort to improve the ability of health-care providers to monitor patients while reducing their exposure to SARS-CoV-2. Both hyperglycaemia and hypoglycaemia are associated with poor survival in patients with COVID-19. Fasting blood glucose concentration in patients with COVID-19 with or without diabetes at admission was a strong predictor of death among patients directly admitted to ICU, and severe hyperglycaemia after admission was a strong predictor of death among patients not in ICU. Almost 50% of hospitalised patients with COVID-19 were hyperglycaemic and even normoglycaemic patients showed alterations in their glycaemic control, with insulin resistance and an abnormal cytokine profile. It was also found that less variability in glucose excursions measured as time in range was associated with a lower risk of all-cause mortality and cardiovascular mortality among patients with type 2 diabetes. These findings indicate that acute hyperglycaemia and long-term glycaemic control are essential in patients with COVID-19 and that short-term glycaemic control might improve the prognosis; however, it is still not established whether acute hyperglycaemia is an aetiologic factor driving poor prognosis or whether it simply reflects the severity of the disease.

Importance of risk stratification

In addition to a potential risk of developing type 1 diabetes, impairment of islet function in people with metabolic disorders should be considered after infection with SARS-CoV-2. Even without extensive destruction of islets, many patients are likely to need enhanced treatment with insulin to avoid ketoacidosis and hyperglycaemia, both of which need to be closely monitored. Patients with obesity also have an increased insulin requirement due to impaired insulin secretion and increasing insulin resistance, which might contribute to their increased risk of mortality. Furthermore, based on findings from the Recovery Trial, nearly all patients with severe COVID-19 are now receiving dexamethasone, a powerful anti-inflammatory glucocorticoid. Although dexamethasone inhibits inflammation, it is still a matter of debate whether steroid-induced hyperglycaemia, which increases the need for insulin therapy shortly after application (ie, within 4–6 h), is due to impaired insulin secretion,
of COVID-19, regardless of vaccination status, the necessity for adequate control of glycaemia and blood pressure in older populations, even after a successful vaccination programme, has to be maintained with high priority (figure 3).

Long-term consequences and monitoring after COVID-19

Evidence from the outbreak of the closely related SARS-CoV in 2002–03 suggests that there is a likelihood of long-term metabolic sequelae from COVID-19. Long-term metabolic abnormalities have been observed for up to 12 years in survivors of severe acute respiratory syndrome. These abnormalities included dyslipidaemia and cardiovascular disease, as well as signs of abnormal glucose metabolism with insulin resistance, hyperglycaemia, and diabetes.115,116 Furthermore, a chronic post-viral syndrome characterised by chronic fatigue, variable non-specific myalgia, depression, and sleep disorders was observed.115 Similar long-term consequences of COVID-19, termed post-COVID and long COVID syndromes,117 or post-acute sequelae of COVID-19, have been reported.118 It was shown that, beyond the first 30 days of illness, survivors of COVID-19 exhibited a significantly higher risk of death and health resource use.119 In relation to metabolic diseases, a study from Spain, which investigated the long-term outcomes of 766 patients with COVID-19 1 year after hospital discharge, showed that seven (1%) of the 543 patients who were alive after 1 year and provided data had developed new-onset diabetes and that 11 (10%) of the 109 patients who had diabetes had worsening of glycaemic control.120 A study from Italy showed that glycaemic abnormalities could be detected at least 2 months after recovery from COVID-19.121

COVID-19 survivors frequently develop physical, psychosocial, and cognitive impairments that require rehabilitation programmes.116 Prolonged exposure to stressors, such as those experienced through isolation, increases the risk of developing major depression, anxiety, and post-traumatic stress disorders.117 Furthermore, following treatment in ICU, persistent impairment in mental health is commonly described and a high prevalence of depression has been observed.122 It should also be considered that particular therapies affecting expression of ACE2 (eg, ACE inhibitors or angiotensin II receptor blockers) might also influence the RAAS and neuroendocrine stress axis.123 Other unexpected complications can occur after COVID-19, such as invasive fungal sinusitis (mucormycosis), which usually affects people with poor immunity or uncontrolled diabetes.124 Steroid treatment is another risk factor for mucormycosis, meaning that the high doses of steroids administered to patients with severe COVID-19 might induce this side-effect, as shown in India.125

Patients admitted to hospital with COVID-19 will need close monitoring for risk factor control following discharge, with potential use of novel therapies to reduce the risk of medium-term complications.126 A follow-up study of people discharged from hospital following admission with COVID-19 showed that, at a mean follow-up of 140 days, nearly a third of patients were readmitted and 12% had died.126 Follow-up of patients with post-COVID-19 will include assessment and monitoring of cardiovascular and renal complications, and risk factor control. Patients with hyperglycaemia at admission will need follow-up to establish if these patients have new-onset diabetes.

The disproportionate excess risk of mortality from COVID-19 in people with both types of diabetes warrants vaccination prioritisation (panel), a guideline that is included in most national vaccination strategies.18,98 After vaccination, disease management should follow evidence-based guidelines for patients with COVID-19 and type 2 diabetes.127 The rampant spread of COVID-19 in countries with a high prevalence of diabetes, such as India, Turkey and Brazil are undoubtedly of serious concern.143–145 The implications might be far reaching, particularly regarding the care of patients with diabetes or other metabolic diseases, and their outcomes (including mortality). In Africa, the situation is, at the time of writing, seemingly different, despite how the emergence of new SARS-CoV-2 variants is raising concern. Reasons for the lower severity of morbidity and mortality in Africa compared with other world regions might include the young age demographic, quick action, public support, favourable climate, and good community health systems.128 As a region with limited health-care resources, it will be important for Africa, particularly sub-Saharan Africa, to put emphasis on prevention strategies.

Smart disease management during and following the pandemic has been proposed. An integrated model of digital disease management might considerably relieve the burden to ambulatory health care, if it is implemented.
as an interoperable digital solution following evidence-based medical knowledge, operated by addressing the personal needs of patients, and hosted by an approved medical body. This model requires the following considerations: the patient must have access to evidence-based health information in a language adjusted for health literacy, there must be medical indicators representing the therapeutic goal or corridor for patients, such an indicator must be technically measurable, and the patient must have a therapy that can be adjusted by patient self-management. Applying smart digital disease management might have the potential to substantially reduce the throughput in the ambulatory health-care system. This approach could be an option in regions with a fast growing prevalence of patients with chronic diseases or in regions with a reduced density of medical services. Ultimately, this approach to disease management might be the optional virtual solution for ambulatory care in patients with chronic and metabolic diseases during a pandemic.

Conclusions

The COVID-19 pandemic has presented unique challenges for people with metabolic diseases, a patient group with a high risk of severe SARS-CoV-2 infection. Pending definitive evidence regarding the long-term effects of COVID-19 on risk of incident diabetes, the susceptibility of β cells to inflammation and oxidative stress is well supported by clinical and experimental studies. This finding is especially relevant given that β cells are scarce in number yet make up one of the most metabolically active cell types in the human body. There has been increased emphasis on the importance of self-care activities for people with diabetes to optimise their diabetes management; however, this has proven difficult because of restrictions due to lockdown and reduced face-to-face education on diabetes. During the pandemic, we have learned how to optimise pharmacological management, including ICU treatment, for patients with diabetes with or without COVID-19. The pandemic has also presented people with diabetes and their health-care teams with an opportunity to innovate and transition towards increasingly digitalised care, to continue supporting patients from their own homes. Preventative measures, including increased physical activity and enhanced health nutrition, are important in reversing insulin resistance and could be effective in reducing mortality related to COVID-19.

The COVID-19 pandemic has revealed the inherent inertia and limitations of our global health-care systems. It would be a progressive failure not to respond to this alarm signal and change our strategies to help to prevent diabetes and obesity with societal measures, diagnose metabolic syndromes as early as possible, focus on diabetes remission rather than progressive and expensive treatment, and individualise diabetes management to meet sustainable prevention of complications by use of all available evidence and technology. The vulnerability of resource-limited systems, notably in low-income countries and disadvantaged communities with knock-on effects on the global community, calls for urgent action to close these care gaps by reforming the health-care system, which was highlighted in the Lancet Commission on diabetes. The effects of COVID-19 and its follow-up diseases will probably be seen for many years to come. As such, we might have to learn to live with the virus and be aware of possible complications for people at higher risk of severe disease including people with diabetes and other metabolic diseases. The non-communicable pandemic of metabolic disease due to diabetes and obesity, affecting 0·5 billion people worldwide, could be considered as the foundation for the communicable COVID-19 pandemic, which has disproportionately affected this patient group (figure 3).

In high-income countries, there is a high prevalence of metabolic diseases and a high incidence of COVID-19. However, in low-income and middle-income countries, where the prevalence of metabolic diseases is lower, the incidence of COVID-19 is unclear due to underreporting and fewer testing services for SARS-CoV-2. Therefore, a question that still remains to be fully answered is whether the risk of SARS-CoV-2 infection is the same for everybody or whether, based on specific receptor pathways, there is an increased risk of infection for patients with metabolic disease.

Contributors

CS, PEHS, AL, RL, and SRB wrote several sections of the Review. Remaining authors wrote smaller sections of the review. CS and RL prepared the figures. CS, PEHS, and RL prepared the tables. All authors reviewed successive drafts of the Review. All authors approved the final submitted version and had final responsibility for the decision to submit for publication.

Declaration of interests
