Abstract
This paper discusses the manufactured one-axis controlled bearingless motor and its experimental results in liquid nitrogen. The bearingless motor is an axial type bearingless motor. It generates a force in the axial direction to control the axial displacement of the rotor and a rotation torque for the motor. The axial displacement is actively controlled using a PID controller, and the rotation speed of the rotor is also actively controlled using a PI controller. The other degrees of freedom are passively supported by the repulsive force of the permanent magnet bearings. The axial type bearingless motor consists of a stator, a rotor, three displacement sensors, and three Hall sensors. Displacement sensors and Hall sensors are used to measure the axial displacement and rotation angle of the rotor. The stator has six salient poles, and the rotor has four poles with four permanent magnets. The air gap between the stator and rotor is 1.5 mm at the center position. The axial type bearingless motor and permanent magnet bearings are set in liquid nitrogen in the experiment. The experimental results show an impulse response at 0 rpm, the relationship between the displacement of the rotor and rotation speed, the relationship between the driving current and the rotation speeds, and a step response from 500 rpm to 1,000 rpm in the rotation speed. From experimental results, it is confirmed the stable levitation and rotation of the bearingless motor at liquid nitrogen temperature.

Keywords: Magnetic bearing, Bearingless motor, Actuator, Rotary machinery, Centrifugal pump

1. Introduction

Liquefied natural gas and liquid hydrogen are expected as alternative energy for petroleum (Ministry of Economy, Trade and Industry). These liquids require a pump with a dedicated bearing for low temperature liquids below 100K. Ceramic ball bearings are used in conventional cryogenic centrifugal pumps but frequent maintenance requirements due to bearing wear problems. To solve this problem, a cryogenic centrifugal pump using a magnetic bearing has been developed (Komori, et al., 2004, 2017) (Okada, et al., 2014). They solve the problem by supporting the rotor in a non-contact support using magnetic bearings or superconductors. A frameless eddy current sensor has also been developed for cryogenic displacement measurement, which are indispensable for magnetic bearings in extremely low temperature (Wang, et al., 2010).

However, magnetic bearings in cryogenic centrifugal pumps are not widely adopted due to the problem of high cost of the magnetic bearings (Okada, et al., 1995). Sensors, controllers, inverters, etc. are required to use magnetic bearings. In response to the cost problem, one-axis controlled bearingless motors or self-bearing motors have been developed (Ueno and Arakawa, 2014) (Ueno, et al., 2000) (Sugimoto, et al., 2016). This reduces the cost of the magnetic bearing by reducing the number of sensors, controllers, and inverters by setting the controlled axis only in the axial direction. Some rotary machines for extremely low temperatures using magnetic bearings have been reported (Komori, et al., 2017) (Okada, et al., 2014), but there are no examples of study on such rotary machines using bearingless motors.

In this paper, we show the results of levitation and rotation experiments in liquid nitrogen (77 K) with fabricating one-axis controlled bearingless motor which is axial type bearingless motor (ABM). The axial direction is actively
controls using ABM and PID controller, and the other four degrees of freedom are passively supported by permanent magnet bearings (PMBs) using the repulsive force of permanent magnets. It confirmed that the ABM is levitated and rotated from 100 rpm to 1,900 rpm in liquid nitrogen.

Fig. 1 Structure of axial type bearingless motor which consists of a stator, a rotor, displacement sensors, and Hall sensors. The PMBs passively control displacements and rotations in the $x$, $y$, $\theta_z$, and $\theta_y$ directions. The coordinate point is the center position of the stator.

![Diagram of bearingless motor](image2.png)

Fig. 2 Schematic drawing and cross-section of (a) the rotor and (b) the stator. The rotor consists of permanent magnet for PMBs and ABM, rotor core and shaft. The stator consists of Electromagnets and a stator core.

2. Structure

2.1 Bearingless motor

The structure of ABM is shown in Fig. 1. It consists of a stator, a rotor, three displacement sensors, and three Hall sensors. The rotor is levitated using the ABM and two permanent magnet bearings (PMBs) and rotates around the $z$ axis using the ABM. The ABM generates a force in the $z$ direction and a rotating torque in the $\theta_z$ direction of rotation to the rotor. Displacement sensors and Hall sensors are set to measure the axial displacement and rotation angle of the rotor. The displacement in the $z$ direction is actively controlled using PID controller. The rotation speed in the $\theta_z$ direction is also actively controlled using PI controller. The $x$ and $y$ displacement and the $\theta_x$ and $\theta_y$ rotation angle are passively...
supported by the radial repulsive force in the PMBs. The permanent magnet forces in the ABM and PMBs are balanced when the rotor is in the center position.

Figure 2 shows a schematic drawing and cross-section of the rotor and the stator. Eight permanent magnets (PMs) are set to be 4-pole for ABM as shown in Fig. 2(a). Four PMs are set on both ends of the rotor for PMBs. The axis of rotation of the rotor is in the z direction. The stator consists of an iron core and twelve electromagnets of a concentrated winding as shown in Fig. 2(b). Three Hall sensors are set to detect the rotation angle in the $\theta_2$ at 60 degree intervals between electromagnets. The stator has six salient poles on one side, and the rotor has four poles with four PMs.

Parameters of the ABM are shown in Table 1. The material of the rotor and stator core is pure iron. The stator is 50 mm in outer diameter, 40 mm in inner diameter and 40 mm in height. The gap between slots of the stator is 7 mm in width and 15 mm in depth. The rotor is 50 mm in outer diameter and 126 mm in height. The air gap is 1.5 mm between PM of ABM and top of electromagnets. The PM of ABM is NdFeB (N40), 25 mm in outer radius, 20 mm in inner radius, 1.0 mm in height, 90 degrees in central angle. Electromagnet is 0.3 mm in wire diameter, 250 turns. Detailed dimensions of the rotor and stator are shown in Fig. 3 and Fig. 4.
2.2 FEM analysis and experimental result of PMB

PMB consists of 4 ring-shaped PMs: 2 PMs attached to the stator and 2 PMs attached to the rotor. Since these PMs are magnetized in the direction of the arrow in Fig. 5, the repulsive force of the PMs is generated in the radial and axial directions. JMAG Designer version 10 was used for FEM analysis. A calculated result and an experimental result of the repulsive force are shown in Fig. 6 and Fig. 7. Figure 6 shows the repulsive force in the radial direction. The calculated result shows that the repulsive force is 11.7 N/mm, and the experimental result is 13.1 N/mm. This repulsive force is the radial restoring force of the rotor. Figure 7 shows the axial repulsive force. The calculated result shows that the repulsive force is 19.5 N/mm, and the experimental result is 18.7 N/mm. This repulsive force is the unbalanced force of the rotor.

Table 2 shows the PMB parameters. The material is NdFeB, and the rotor PM is 8.0 mm in the outer diameter, 4.0 mm in the inner diameter, and 5.0 mm in the height. The stator PM is 15 mm in the outer diameter, 10 mm in the inner diameter, and 5.0 mm in the height. The air gap between the stator PM and the rotor PM is 1 mm.
2.3 Control system

A block diagram of the control system is shown in Fig. 8. It consists of electromagnets, a rotor, hall sensors, displacement sensors, power amplifiers, sensor amplifiers, analog-to-digital converter, digital-to-analog converter, and a controller. Hall sensors are used to detect the rotation angle and rotation speed. Displacement sensors are used to detect the displacement of the rotor in the $z$ direction. Electromagnets, the rotor, hall sensors, and displacement sensors are set in liquid nitrogen temperature. Power amplifiers, sensor amplifiers, the analog-to-digital converter, the digital-to-analog converter, and the controller are used at room temperature. The controller was implemented using a digital signal processor (DS1104). The DSP sampling period is set at 100μs.

Figure 9 (a) shows a block diagram of the controller. The $z_0$ is target value of displacement of the rotor, the $z$ is the displacement in the $z$ direction, the $	heta_z$ is the rotation angle of the rotor, the $\varphi$ is the center angle of the electromagnet, the $\omega_0$ is target value of rotation speed, the $\omega$ is the rotation speed of the rotor.

Hall sensors are used to detect the rotation angle and rotation speed of the rotor. Displacement sensors are used to detect the displacement of the rotor in the $z$ direction.

Fig. 9  Block diagram of the controller. The $z_0$ is target value of displacement of the rotor, the $z$ is the displacement in the $z$ direction, the $\theta_z$ is the rotation angle of the rotor, the $\varphi$ is the center angle of the electromagnet, the $\omega_0$ is target value of rotation speed, the $\omega$ is the rotation speed of the rotor.
degree intervals from 0 degree to 300 degree.

In extremely low temperatures, the output of displacement sensor changes significantly compared to room temperature because of the reduction of a sensing coil resistance. For this reason, the sensor output is corrected for the change and adjusted to the same characteristics as room temperature in liquid nitrogen. Also, different values are used for PID gain and PI gain in room temperature and liquid nitrogen because of changes in the surface magnetic flux density of PMs and the permeability of the iron core.

3. Experimental setup

The experiment was carried out in liquid nitrogen to confirm the stability of the ABM under extremely low temperature. The stator, the rotor, displacement sensors, Hall sensors, and PMBs are set in liquid nitrogen. The photograph of the experiment and the photograph of the ABM and PMBs are shown in Fig. 10 and Fig. 11. Levitation
and rotation experiments are carried out with this setting. The ABM is set in liquid nitrogen, displacement and Hall sensors also are under liquid nitrogen temperature. The change in temperature affects the output of the displacement sensors and Hall sensors. This change is measured and corrected before the experiment.

In the levitation experiment, the impulse response is measured to confirm the stability of the rotor at 0 rpm. In rotation experiments, the rotor vibration and the driving current are measured between 100 rpm and 1,900 rpm. A step response from 500 rpm to 1,000 rpm and the rotor displacement at that time are also measured.

The PID gain of levitation control is shown in Table 3, $5.3 \times 10^3 \text{A/m}$ in proportional gain, $0.020 \times 10^3 \text{A/s/m}$ in differential gain, $3.0 \times 10^3 \text{A/(m/s)}$ in integral gain. The PI gain of rotation speed control is shown in Table 4, $1.0 \times 10^{-3} \text{A/rpm}$ in proportional gain, $1.0 \times 10^{-3} \text{A/(rpm/s)}$ in integral gain. Physical parameters of the rotor are shown in Table 5, 0.159 kg in mass, $2.98 \times 10^{-5} \text{kg/m}^2$ in a moment of inertia around $z$ axis at a center point of the rotor, $1.35 \times 10^{-4} \text{kg/m}^2$ in a moment of inertia around $x$ and $y$ axis at a center point of the rotor.

![Displacement vs. Time](image1)

**Fig. 12** Relationship between the displacement of the rotor in the $z$ direction and time. The maximum displacement is 84 $\mu$m at 8.8 ms. The vibration has converged to the target position within 80 ms. The natural period is about 93 Hz.

![Displacement vs. Rotation Speed](image2)

**Fig. 13** Relationship between the displacement of the rotor in the $z$ direction and the rotation speed. The displacement is 130 $\mu$m at 400 rpm, 160 $\mu$m at 850 rpm.

![Driving Current vs. Rotation Speed](image3)

**Fig. 14** Relationship between the current of electromagnets and the rotation speed. The driving current is 42 mA at 100 rpm and 552 mA at 1,900 rpm.
4. Experimental results

First, the impulse response is measured at 0 rpm in a state where ABM and PMBs are set in liquid nitrogen. The relationship between the displacement in the $z$ direction and time is shown in Fig. 12. The impulse disturbance is applied at 0 seconds. The maximum displacement is 84 μm at 8.8 ms. The vibration has converged to the target position within 80 ms. The natural period is about 93 Hz.

Next, the rotation test is carried out to confirm the stability of ABM in liquid nitrogen. The relationship between the displacement of the rotor in the $z$ direction and the rotation speed is shown in Fig. 13. The rotor is levitated and rotated from 100 rpm to 1,900 rpm. The maximum displacement is 160 μm peak to peak at 850 rpm. The second largest displacement is 130 μm peak to peak at 400 rpm. These displacements are lower than the air gap of ABM that is 1.5mm. The stability of the rotor from 100 rpm to 1,900 rpm is confirmed. The cause of peaks at 400 rpm and 850 rpm is due to a cogging torque of the ABM because the rotation speed is considerably lower than the natural period of the rotor.

Figure 14 shows the relationship between the current of electromagnets and the rotation speed. The relationship is clearly linear. The minimum driving current is 42 mA at 100 rpm. The maximum driving current is 552 mA at 1,900 rpm. The relationship between rotation speed and driving current is 0.277 mA/rpm. The cause of the increase in drive current around 850 rpm is considered to be due to the energy lost by the vibration of the rotor.

Figure 15 shows the result of a step response test of the motor. The relationship between the rotation speed and time is shown in (a), and the relationship between the displacement and time is shown in (b). The reference speed of rotation speed is changed from 500 rpm to 1,000 rpm at 0 seconds. The rotation speed has reached the reference speed at 64 ms.
5. Conclusion

The one-axis active controlled bearingless motor was developed, and the stability of rotor displacement in liquid nitrogen was measured. The ABM generates a force in the axial direction to control the axial displacement of the rotor and a rotation torque for the motor. The axial displacement is actively controlled using a PID controller, and the rotation speed of the rotor is also actively controlled using a PI controller. The other degrees of freedom are passively supported by the repulsive force of the permanent magnet bearings. From the experiments, it is confirmed that the ABM is levitated and rotated in liquid nitrogen. The rotor is rotated from 100 rpm to 1,900 rpm. The maximum displacement in the z direction is 160 μm peak to peak at 850 rpm. The driving current is 552 mA at 1,900 rpm. The rotation speed has reached from 500 rpm to 1,000 rpm within 64 ms.

Sensor output and shaft rigidity change due to changes in physical properties at extremely low temperatures, but the bearingless motor was operated stably in liquid nitrogen by adjusting the sensor output and PID gain. From experimental results, the vibration of the rotating rotor was sufficiently small for the air gap. The drive current was linear with its rotation speed of the rotor. The step response from 500 rpm to 1,000 rpm reached 1,000 rpm at 64 ms. At that time, the rotor was displaced due to the influence of the drive current. The displacement immediately recovered to the center position and the rotor was levitated and rotated stably.
