Intracellular calcium controls several crucial cellular events in apicomplexan parasites, including protein secretion, motility, and invasion into and egress from host cells. The plant compound thapsigargin inhibits the sarcoplasmic-endoplasmic reticulum calcium ATPase (SERCA), resulting in elevated calcium and induction of protein secretion in *Toxoplasma gondii*. Artemisinins are natural products that show potent and selective activity against parasites, making them useful for the treatment of malaria. While the mechanism of action is uncertain, previous studies have suggested that artemisinin may inhibit SERCA, thus disrupting calcium homeostasis. We cloned the single-copy gene encoding SERCA in *T. gondii* (TgSERCA) and demonstrate that the protein localizes to the endoplasmic reticulum in the parasite. In extracellular parasites, TgSERCA partially relocates to the apical pole, a highly active site for regulated secretion of micronemes. TgSERCA complemented a calcium ATPase-defective yeast mutant, and this activity was inhibited by either thapsigargin or artemisinin. Treatment of *T. gondii* with artemisinin triggered calcium-dependent secretion of microneme proteins, similar to the SERCA inhibitor thapsigargin. Artemisinin treatment also altered intracellular calcium in parasites by increasing the periodicity of calcium oscillations and inducing recurrent, strong calcium spikes, as imaged using Fluo-4 labeling. Collectively, these results demonstrate that artemisinin perturbs calcium homeostasis in *T. gondii*, supporting the idea that Ca2+-ATPases are potential drug targets in parasites.

Apicomplexan parasites infect a wide range of animals, including humans, using a process of active penetration of their host cells (41). This important group of parasites includes *Plasmodium* spp., the causative agents of malaria, and the opportunistic pathogens *Cryptosporidium* spp. and *Toxoplasma gondii*. Host cell invasion by these parasites relies on regulated secretion of adhesins from apical secretory organelles called micronemes (3). Microneme secretion in *T. gondii* is governed by changes in cytosolic calcium ([Ca2+]i) levels in the parasite, which control gliding motility, cell invasion, and egress (6, 27, 34, 48). Similar studies have demonstrated a role for [Ca2+]i in secretion and motility by *Cryptosporidium parvum* (7) and *Plasmodium berghei* (14). Although these previous studies indicate an important role for alterations in [Ca2+]i, the molecular mechanisms controlling calcium signaling in parasites are not well understood.

In eukaryotic cells, [Ca2+]i is maintained at an ~10,000 lower level than the extracellular environment (1). A system of calcium channels and pumps maintains this steep gradient and allows for selective increases in [Ca2+]i, which function as a second messenger (1). Apicomplexans are also capable of maintaining a steep calcium gradient with low resting levels of [Ca2+]i. Quantitative measurements using fura-2 in *T. gondii* indicate that [Ca2+]i levels are ~100 nM in resting cells (33). Apicomplexans possess several stores of calcium, including acidocalcisomes, the mitochondrion, and the endoplasmic reticulum (ER) (32). Of these potential calcium stores, the ER is the most likely source for rapid release and reuptake of calcium needed to control secretion and motility. Previous studies using pharmacological inhibitors indicate that *T. gondii* responds to agonists of both IP3 and ryanodine-type receptors and that stimulation of these channels releases Ca2+ and stimulates parasite gliding and microneme secretion (8, 26). Perturbation of [Ca2+]i levels not only blocks secretion but also prevents motility and cell invasion (27). Fluorescent imaging studies using calcium-sensitive dyes have revealed that [Ca2+]i levels in the parasite oscillate during parasite gliding (27, 49) and are elevated during host cell contact (48). However, a prolonged increase of calcium is toxic as shown by treatment with caffeine, which elevates [Ca2+]i, and abolishes the natural oscillations in calcium seen in motile parasites (49). These findings indicate an important role for reuptake of calcium to dampen signaling and refill intracellular stores.

Recent phylogenetic analysis of the apicomplexan genomes (i.e., *Plasmodium*, *Cryptosporidium*, and *Toxoplasma*) indicates highly conserved complement of P-type Ca2+ ATPases (36). These particular apicomplexan contain a single orthologue each of the sarcoplasmic ER Ca2+ ATPase (SERCA), also referred to as ATPase6 in *P. falciparum* (21). These apicomplexans also contain an orthologue of the yeast PMR1 transporter (36), which has previously been called ATPase4 in *P. falciparum*, where it is reported to localize to the plasma membrane of asexual stages (11). In addition, apicomplexans contain several additional Golgi-ER-type Ca2+ ATPases and a single Ca2+/H+ exchanger (36). The precise roles played by these Ca2+ ATPases in calcium homeostasis and signaling have not been addressed by functional studies. Uniquely, *T. gondii*

contains two plasma membrane-type Ca\(^{2+}\)-ATPases, which are apparently absent from Plasmodium and Cryptosporidium. One of these genes, TgA1 (named for T. gondii plasma membrane calcium ATPase 1), has previously been characterized as a component of both the plasma membrane and the acidicocli-
some (29). Disruption of TgA1 leads to decreased polyphos-
phate content, increases in basal [Ca\(^{2+}\)], and impaired inva-
sion (28), demonstrating that calcium homeostasis is critical for intracellular survival.

SERCA is one of best characterized P-type ATPases, which are defined by the existence of a phosphorylated intermediate during their catalytic cycle (50). Each SERCA protein trans-
ports two Ca\(^{2+}\) ions from the cytoplasm to the lumen of the ER using the energy from hydrolysis of one ATP molecule (44). SERCA consists of 10 transmembrane regions (M1 to M10) and three cytoplasmic domains (A domain, actuator; N domain, nucleotide binding; and P domain, phosphorylation) (46). The reaction mechanism involves transformation be-
tween two conformational states known as E1 and E2, result-
ing in binding of calcium on the cytoplasmic side and release into the lumen of the ER (44, 50). Thapsigargin, a sesquiter-
penyl lactone produced by the plant Thapsia garganica, locks the protein in the E2 form, which has a lower affinity for calcium, thus blocking activity (38, 39, 43).

Artemisinin is also a sesquiterpene lactone that is produced by the plant Artemisia annua. Artemisinin and related com-
ounds such as artemether and artesunate contain an endo-
peroxide ring that is crucial for activity (18). In Plasmodium, the SERCA orthologue, PfATP6, was proposed as a target of the antimalarial drug artemisinin, based on heterologous ex-
pression studies in Xenopus oocytes (12). Artemisinins also

T. gondii in vitro; however, they are not used clinically to treat toxoplasmosis due to relatively low efficacy (19, 20, 40).

To explore the molecular mechanism of inhibition by ar-
temisinin, we cloned the SERCA homologue of T. gondii (TgSERCA), demonstrated it functions as a Ca\(^{2+}\) ATPase, and tested its sensitivity to artemisinin.

**MATERIALS AND METHODS**

**Compounds.** Artemisinin (98% pure) (CID: 452191), thapsigargin (>90% pure) (CID: 532192), and caffeine (98% pure) (CID: 64119) were obtained from Sigma (St. Louis, MO). BAPTA and BAPTA-AM (>95% pure) were obtained from Molecular Probes (Invitrogen, Carlsbad, CA). Compounds were dissolved in dimethyl sulfoxide (DMSO; Sigma) and stored at −80°C until use.

**Parasites and culture.** T. gondii strain RH (ATCC 50583), clone 2F (ATCC 50583) that expresses bacterial β-galactosidase (10) was propagated as described previously (27). Briefly, freshly egressed parasites were labeled with 250 nM Fluoro-4-AM (Molecular Probes) for 5 to 10 min at room tempera-
ture, followed by centrifugation at 400 × g for 5 min and washing in Ringer’s solution. Parasites were then incubated for 30 min at 37°C in the presence of 1 μM Thapsigargin (Thornwood, NJ) equipped for epifluorescence microscopy (DAPI [4',6-diamidino-2-phenylindole], fluorescein isothiocyanate, and Texas Red filter cubes [Chroma Technology Corp., Rockingham, VT]). Images were acquired by using a 1.4 NA 100× Plan-Apochromat lens, captured by an AxiosCam MRm CCD camera.
(Zeiss), and processed by using Axiosvision software v4.5 (Zeiss). Images were deconvolved by using an inverse filter algorithm.

**Electron microscopy.** For immuno-electron microscopy, parasites were fixed in 4% paraformaldehyde (Polysciences, Inc., Warrington, PA) in 100 mM phosphate buffer (pH 7.2) for 30 min at room temperature. Immunolabeling and silver enhancement were carried out prior to embedding as follows. Fixed parasites were washed in blocking buffer (5% FBS, 5% normal goat serum, 0.05% saponin, 100 mM phosphate) and subsequently incubated for 30 min with mouse anti-SERCA or rabbit anti-GFP antibodies (ab6556; AbCam, Inc., Cambridge, MA) diluted in blocking buffer. Samples were washed in phosphate buffer and probed for 30 min with nanogold anti-mouse or anti-rabbit conjugates (Nanoprobes, Yaphank, NY) diluted in blocking buffer. Samples were washed in phosphate buffer and fixed for 15 min with 1% glutaraldehyde (Polysciences) in phosphate buffer. Samples were silver enhanced for 10 min by using an LJ silver enhancement kit (Nanoprobes), washed in water, embedded in 10% gelatin, and infiltrated overnight with 2.3 M sucrose and 20% polyvinylpyrrolidone in PIPES [piperazine-N,N’-bis(2-ethanesulfonic acid)]–MgCl₂ at 4°C. Samples were trimmed, frozen in liquid nitrogen, and sectioned with a Leica Ultracut UCT cryo-ultramicrotome (Leica Microsystems, Inc., Bannockburn, IL). Ultrathin sections (~70 nm) were stained with 0.3% uranyl acetate and 2% methylcellulose and then viewed with a JEOL 1200EX transmission electron microscope (JEOL USA, Inc., Peabody, MA).

**MIC2 secretion assay.** Microneme secretion assays were performed as described previously (5, 26). Briefly, freshly egressed parasites were suspended in assay medium (Dulbecco modified Eagle medium with 44 mM sodium bicarbonate, 20 mM HEPES, 2 mM glutamine, 10 μg of gentamicin/ml, and 3% FBS) and treated with different concentrations of calcium agonists for 5 or 10 min at 18°C. In some experiments, parasites were pretreated with 50 μM BAPTA-AM or 1 mM BAPTA (Molecular Probes) for 20 min at 18°C to chelate intracellular and extracellular calcium, respectively, or with DMSO. Treated cells were then incubated for 10 min at 18°C with 10 μM artemisinin or 1% ethanol as a positive control. After treatments, parasites were transferred to 37°C for 2 min to allow secretion, chilled on wet ice, and separated into the supernatant and cell pellet by centrifugation at 400 g.

**RESULTS**

**Characterization of TgSERCA.** To identify the SERCA ortholog from *T. gondii* (*TgSERCA*), *A. thaliana*, and *P. falciparum* SERCA orthologues were used to search the *T. gondii* genome database (http://www.toxodb.org/) using TBLASTN. A single SERCA homologue identified in *T. gondii* (Draft 3 annotation 44.m02594) shared more than 50% identity with human, plant, and *Plasmodium* orthologues (see Fig. S1 in the supplemental material). The full-length sequence was determined from amplified CDNA of the RH strain and the resulting predicted protein sequence was deposited in GenBank (AAU93917). Comparison of the predicted secondary structures and domain architectures revealed that *TgSERCA* contained 10 transmembrane regions similar to human and *Plasmodium* orthologues (Fig. 1A). *TgSERCA* also contained conserved domains found in E1-E2 type calcium ATPases, including a cation-transporting ATPase N-terminal domain (InterProScan: IPR04014), an E1-E2 ATPase domain (IPR008250), a halocid dehalogenase-like hydrolase domain (IPR005834), and a cation-transporting ATPase C-terminal domain (IPR006068, Fig. 1B). *TgSERCA* also contained conserved amino acid residues that are predicted to form the Ca²⁺-binding and ATP-binding pockets (42, 45, 46) (Fig. 1B).

**Localization of TgSERCA to the ER in *T. gondii*.** To investigate the localization of TgSERCA, we generated an anti-TgSERCA polyclonal antiserum to the phosphorylation (P) and nucleotide binding (N) domains expressed as a recombinant protein in *E. coli* (see Materials and Methods). Anti-TgSERCA sera recognized a single band in parasite cells at around 120 kDa, which corresponds to the estimated Mr of TgSERCA, but did not cross-react with host cells by Western blotting (Fig. 2A). Anti-TgSERCA antiserum was used for immunofluorescence microscopy of the *T. gondii* RH strain expressing GFP-HDEL, which serves as an ER marker (17). In intracellular parasites, TgSERCA and GFP-HDEL were localized primarily surrounding the nucleus of the parasite and extending into the cytoplasm (Fig. 2B). The characteristic pattern of this staining and colocalization with GFP-HDEL indicated that TgSERCA is likely localized in the ER in intracellular parasites. However, in extracellular parasites, TgSERCA had partially relocalized to the apical region in a pattern that was nonoverlapping with GFP-HDEL (Fig. 2C). A similar re-
result was obtained using anti-GFP antibody to localize GFP-HDEL (data not shown).

The distribution pattern of SERCA in *T. gondii* parasites does not resemble micronemes, rhoptries or dense granules, a result confirmed by electron microscopy below. To determine whether the vesicular structures stained with anti-TgSERCA were mitochondria, we costained *T. gondii* parasites with anti-TgSERCA antibody and the mitochondrial marker, MitoTracker. The mitochondrion in *T. gondii* was observed as single tube-like structure as reported previously (30), and this signal did not colocalize with that of anti-TgSERCA antibody (Fig. 2D). Furthermore, we investigated whether the staining pattern of TgSERCA was similar to acidocalcisomes, which contain high levels of Ca\(^{2+}\) (29). The staining pattern with anti-vacuolar-ATPase, an acidocalcisome marker (29), revealed small punctate vesicles that did not appear to be similar to the extended membranous structures stained with anti-TgSERCA (Fig. 2E). Although we were unable to perform costaining studies due to the fact that both antibodies were produced in mice, we interpret this result to indicate that TgSERCA is not localized appreciably to acidocalcisomes. Collectively, these results indicate that in intracellular parasites TgSERCA was largely localized in the ER with GFP-HDEL, whereas in extracellular parasites TgSERCA was partially relocalized in a distinct apical membrane compartment.

To further explore the localization of TgSERCA, we performed cryo-immuno-electron microscopy labeling of *T. gondii*. The epitopes recognized by the mouse anti-TgSERCA proved to be extremely sensitive to fixation, precluding post-processing immunolabeling (data not shown). Instead, we

---

**FIG. 2.** Localization of TgSERCA in *T. gondii*. (A) Western blot with anti-TgSERCA antibody against *T. gondii* lysate (Tg) revealed a single band of 120 kDa, while HFF cell lysate (HFF) was negative. (B) Immunofluorescence staining of intracellular *T. gondii*. Intracellular parasites expressing GFP-HDEL were stained with anti-TgSERCA, followed by Alexa-594-conjugated goat anti-mouse IgG (red). The middle panel shows the signal of GFP-HDEL (green), with a merged image shown at the right. Nuclei were stained with DAPI (blue). Bar, 5 µm. (C) Localization of TgSERCA and GFP-HDEL in extracellular parasites. Panels: left, anti-TgSERCA (red, stained as in panel B); middle, GFP-HDEL (green); right, merged image. Nuclei were stained with DAPI (blue). Bar, 2 µm. (D) Localization of TgSERCA and mitochondrion in extracellular parasites. Panels: left, stained with mouse anti-TgSERCA followed by Alexa-488-conjugated goat anti-mouse IgG (green); middle, MitoTracker (red), right, merged image. Nuclei were stained with DAPI (blue). Bar, 2 µm. (E) Localization of TgSERCA (upper) and acidocalcisomes (lower) in separate extracellular parasites. The upper panel was stained with mouse anti-TgSERCA, followed by goat anti-mouse IgG; the lower panel was stained with anti-V-ATPase, followed by goat anti-mouse IgG. Bar, 2 µm. Wide field images were acquired and deconvolved as described in Materials and Methods. A single mid-Z plane is shown for each example.
we used the yeast mutant strain K616, which is defective in determining whether TgSERCA functions as a Ca$^{2+}$ pump. We used the yeast mutant strain K616, which is defective in determining whether TgSERCA functions as a Ca$^{2+}$ pump. The ultrastructural morphology of secretory organelles in T. gondii is quite distinct, and no specific staining of micronemes, dense granules, or rhoptries was observed by cryo-immuno-electron microscopy labeling (Fig. 3D and data not shown). Control sections stained with an isotype control antibody remained negative, confirming the specificity of this technique (Fig. 3E).

**Heterologous expression and activity of TgSERCA.** To determine whether TgSERCA functions as a Ca$^{2+}$ transporter, we used the yeast mutant strain K616, which is defective in both Golgi (PMR1) and vacuolar (PMC1) Ca$^{2+}$ pumps and also lacks calcineurin (CNB1) (9). Previous reports have shown that plant (25) and trypanosomal (13) SERCA orthologues complement the growth of this mutant yeast strain in low-Ca$^{2+}$ medium. The K616 mutant yeast was transfected with TgSERCA, and growth was observed in low-calcium medium containing EGTA. TgSERCA complemented the growth of the K616 yeast strain in low-Ca$^{2+}$ medium with a maximum effect seen when growth was inhibited by 10 mM EGTA (Fig. 4A). Thapsigargin, which is a potent SERCA inhibitor (38), reversed the growth complementing effect of TgSERCA, while treatment of yeast cells containing a vector control had no effect (Fig. 4B). The complementing effects of TgSERCA were not reversed by treatment with caffeine (Fig. 4C), which does not act directly on TgSERCA, but rather activates a ryanodine-type calcium release channel (26). Caffeine is known to enter yeast cells efficiently and to affect kinase signaling (23), although yeast cells lack ryanodine-responsive calcium channels. We also tested the effects of artemisinin treatment on the ability of TgSERCA to rescue the K616 mutant yeast grown in low calcium. The complementation of K616 yeast mutants grown in low calcium was blocked by treatment with artemisinin (Fig. 4D), a finding consistent with TgSERCA being inhibited by this compound. Yeast cells containing the vector alone were not inhibited by treatment with similar levels of artemisinin (Fig. 4D). These findings support a functional role for TgSERCA in restoring calcium homeostasis in this defective yeast strain. Similar results have been obtained by previous studies that have used this yeast mutant to study Ca$^{2+}$ ATPases from T. cruzi (13) and from plants (25).

**Artemisinin does not affect mitochondrial membrane potential in T. gondii.** A recent report indicated that treatment of artemisinin causes substantial loss of mitochondrial membrane potential in S. cerevisiae, albeit at very high concentrations (24). Consequently, we investigated whether a similar event occurs in T. gondii using rhodamine-123, which monitors mitochondrial membrane potential. Treatment of T. gondii with a high dose of artemisinin (100 μM) for 2 h did not alter membrane potential (Fig. 4E), although significant loss was previously reported by treatment with 8 μM artemisinin in yeast (24). Furthermore, no difference was observed in the mitochondrial potential of T. gondii after incubation with 100 μM artemisinin for 6 h (data not shown). These results indicate that the mitochondrion is not a primary target of artemisinin in T. gondii.

**Artemisinin induces calcium-dependent secretion in T. gondii.** Microneme secretion in T. gondii is triggered by elevated cytosolic calcium as shown by detection of the soluble form of MIC2 that is shed into the supernatant following release onto the cell surface and proteolytic cleavage (4, 5). Inhibition of TgSERCA by treatment with thapsigargin results in elevated [Ca$^{2+}$], which stimulates microneme secretion (6, 33). We investigated whether treatment with artemisinin would induce a similar exocytic response by examining cell supernatants for the presence of shed MIC2 by Western blotting. Artemisinin induced the secretion of MIC2 in 5 min when treated with 100 μM, while treatment with lower doses (10 μM) required 10 min to detect secretion (Fig. 5A). This effect was similar, albeit less potent, than that seen with thapsigargin or ethanol (4), two positives controls that have been validated in this assay previously (Fig. 5A). The detection of cellular MIC2 in the cell pellet served both as a loading control and to verify that the effects were not due to lysis, which would have resulted in loss from this fraction (Fig. 5A). Next, we tested whether this induction was dependent on cytosolic Ca$^{2+}$. Secretion of MIC2 by artemisinin was completely reversed by pretreatment with BAPTA-AM, which is a membrane-permeable Ca$^{2+}$ chelator (Fig. 5B). On the other hand, the membrane-impermeable Ca$^{2+}$ chelator, BAPTA, had only a modest affect on secretion (Fig. 5B). These results indicate that artemisinin induces the secretion of microneme proteins through a pathway that is largely dependent on mobilization of intracellular calcium.

**Artemisinin induced calcium spikes in T. gondii.** Previous studies have demonstrated that cytoplasmic calcium levels in T. gondii undergo oscillations that are associated with gliding motility (27, 49). We used Fluo-4 imaging to evaluate the effects of artemisinin treatment on intracellular calcium oscillations in T. gondii. Fluo-4 has the advantage of being very sensitive and rapid, thus making it ideal for temporal measurements, although it is not ratiometric and thus not useful for measuring calcium concentrations (15). Time-lapse video microscopy was used to monitor temporal changes in intracellular calcium after the addition of artemisinin to Fluo-4-labeled parasites. Representative traces derived from time-lapse recordings are shown in Fig. 6. Treatment with 10 μM artemisinin resulted in rapid, repeated oscillations that showed amplitudes similar to those for control parasites (Fig. 6A) but with an increased periodicity (shorter time between repeated cycles) (Fig. 6B). In parasites treated with 50 μM artemisinin, a second pattern was observed, consisting of strong increases (>4-fold) that appeared quite suddenly and which lasted longer and were spaced further apart (increased period) compared to control cells (Fig. 6B). In previous studies, it was observed that calcium oscillations were most commonly observed in cells undergoing gliding (27). However, artemisinin treatment also induced oscillations in nonmotile cells. A high frequency of total cells responded (up to 50% of the population), and yet responses were not synchronous and at any given time only 5 to 10% of cells exhibited oscillations. Removal of...
FIG. 3. Immuno-electron microscopy localization of TgSERCA versus GFP-HDEL in T. gondii. TgSERCA localized to perinuclear ER in both intracellular and extracellular parasites. In extracellular parasites, SERCA labeling extended into the apical region of parasites where it was associated with vesicular structures (apical region indicated by arrows). (A) Intracellular T. gondii immunolabeled with mouse anti-TgSERCA antibody. (B) Extracellular T. gondii immunolabeled with mouse anti-TgSERCA antibody. (C) Intracellular T. gondii expressing GFP-HDEL immunolabeled with rabbit anti-GFP antibody. (D) Extracellular T. gondii expressing GFP-HDEL immunolabeled with rabbit anti-GFP antibody. (E) Intracellular T. gondii immunolabeled with isotype control antibody. N, parasite nucleus; DG, dense granules; G, position of the Golgi. Scale bars, 0.5 μm. Note that the variable size of gold particles seen here is due to the silver enhancement technique. To facilitate identification of gold particles, representative clusters are highlighted by red circles.
extracellular calcium from the medium and addition of 5 mM EGTA did not affect the amplitude or periodicity of calcium oscillations in control or artemisinin-treated cells (data not shown), indicating that the source of calcium is from the release of intracellular stores.

In parasites treated with thapsigargin, altered calcium oscillations were also observed (Fig. 6C), although there were several differences from the responses seen with artemisinin. First, the average level of intracellular calcium was elevated by thapsigargin (Fig. 6), a result not seen with artemisinin. Second, thapsigargin induced both slow calcium spikes with higher amplitude and longer periodicity and short, rapid oscillations (Fig. 6C). Finally, the effects of thapsigargin were noted at doses of 0.5 μM, ≤10-fold lower than similar responses seen with artemisinin (Fig. 6).

To provide a more complete summary of the changes in calcium oscillations, ~25 individual time lapse recordings were analyzed for each condition to determine the time interval between each cycle (period), and the data were plotted as a histogram (Fig. 6D). Changes in the periodicity of calcium oscillations that were induced by artemisinin were very apparent. Treatment with 10 μM artemisinin resulted in a faster periodicity with an average time of 13.95 s (±3.5) for control cells (Fig. 6D). In contrast, treatment with low thapsigargin resulted in two responses: cells that responded with average cycles of 21 to 30 s, similar to controls, and cells that exhibited strong calcium spikes that lasted much longer (Fig. 6D). This biphasic pattern resulted in an average period of 33.8 s (±15.6). Finally, treatment with low

FIG. 5. Induction of MIC2 secretion by extracellular parasites as detected by Western blotting of cell fractions. (A) Treatment with artemisinin causes a dose-dependent release of MIC2 into the supernatant (compare 10 μM versus 100 μM at 5 min). Parasites were pretreated with artemisinin (ART), thapsigargin (TG), or 1% of ethanol (EtOH) for 5 or 10 min at 18°C to block premature secretion, followed by stimulation of secretion at 37°C for 2 min. Samples were divided into supernatant and cell pellet and analyzed by Western blotting with anti-MIC2 antibody (supernatant) or anti-β-galactosidase (cell pellet). (B) Chelation of intracellular calcium by BAPTA-AM inhibited secretion induced by artemisinin (ART), while chelation of extracellular calcium by BAPTA had minimal effect. Parasites were pretreated with BAPTA or BAPTA-AM at 18°C for 20 min to chelate calcium, followed by treatment with 10 μM artemisinin or 1% ethanol for 10 min at 18°C, and finally stimulation of secretion at 37°C for 2 min, as detailed in Materials and Methods. Samples were analyzed as in panel A.
doses of thapsigargin (0.5 μM) induced both more rapid, shallow oscillations and longer spikes with greater amplitude, leading to a broad distribution of cycles (Fig. 6D). Collectively, these results confirm that artemisinin and thapsigargin cause similar changes in calcium oscillations, inducing both rapid shallow oscillations and prolonged spikes in intracellular calcium.

**DISCUSSION**

We have explored the function of the Ca$^{2+}$ ATPase SERCA in *T. gondii* in order to determine its role in calcium homeostasis and to investigate the molecular basis of inhibition by several plant sesquiterpene lactones. Our results indicate that *T. gondii* has a single functional SERCA based on the following evidence: (i) BLASTP similarity and phylogenetic grouping with known SERCA enzymes (36), (ii) conserved domain structure and presence of critical Ca$^{2+}$ binding and ATPase residues, (iii) functional rescue of yeast cells defective in Ca$^{2+}$ ATPases, and (iv) inhibition by thapsigargin, a known inhibitor of SERCA Ca$^{2+}$ ATPases (38). TgSERCA is localized to the ER of *T. gondii*, where it likely participates in controlling calcium stores that are important for microneme secretion and motility. We also demonstrate that artemisinin (i) triggers calcium-dependent secretion of microneme proteins in *T. gondii*, (ii) inhibits the functional rescue of yeast mutants expressing TgSERCA, and (iii) induces sustained calcium spikes in *T. gondii*. Collectively, our studies indicate that artemisinin affects calcium homeostasis and signaling in the parasite, supporting the conclusions that it acts as an inhibitor of SERCA.

*T. gondii* has a highly polarized secretory pathway with the ER being an extension of the nuclear envelope: the major site of exit from the ER occurs at the apical surface of the nuclear envelope, leading to a juxtanuclear, stacked Golgi and extending to apical secretory organelles (17). Immunolabeling of TgSERCA confirmed it is located in the ER, where it largely overlaps with GFP containing the C-terminal ER retention sequence HDEL. Surprisingly, the distribution of TgSERCA was somewhat different in extracellular parasites, where the protein was partially found in...
apical membranes that were localized near micronemes. This pattern was not shared by GFP-HDEL, which was retained near the nuclear envelope, suggesting that the ER becomes partitioned in extracellular parasites. Other cells also develop specialized membranes in locations that are important for local calcium control. For example, SERCA orthologues are present in the vacuole in plant cells (37) and alveolar sacks in ciliates (22). The distribution of the TgSERCA-containing vesicles to the apex may be important for rapid release and effective recovery of cytosolic Ca\(^{2+}\), events that likely govern both motility and microneme secretion.

Artemisinin treatment of T. gondii resulted in calcium-dependent secretion of microneme proteins as detected by release of MIC2 into the supernatant, similar to the SERCA inhibitor thapsigargin. While artemisinin treatment was less potent than thapsigargin, it exhibited a dose- and time-dependent induction of microneme secretion in T. gondii. Induction of microneme secretion by both artemisinin and thapsigargin was inhibited by chelation of intracellular calcium, while being much less influenced by extracellular calcium. These results are consistent with both agents acting to release intracellular calcium stores, thus leading to elevated cytosolic calcium that triggers microneme secretion. TgSERCA was shown to complement a yeast strain that is defective in Ca\(^{2+}\) transport, thus establishing it as a functional Ca\(^{2+}\) transporter. TgSERCA expressed in this heterologous system was sensitive to thapsigargin, similar to SERCA orthologues in animal cells. The ability of TgSERCA to complement deficient yeast was also inhibited by artemisinin. The potency of artemisinin in inhibiting the complementation of K616 yeast by TgSERCA and in stimulating parasite secretion was similar, suggesting it acts on the parasite by inhibiting SERCA.

Thapsigargin inhibits SERCA by locking it in the E2 conformation, thus preventing calcium pumping (38, 39). Inhibition of SERCA would be expected to prevent the reuptake into the ER, resulting in higher cytosolic calcium levels. Previous studies of pancreatic B cells have shown that calcium oscillations can be perturbed by thapsigargin, resulting in a pattern of stronger calcium spikes (16). A similar response to treatment with thapsigargin was apparent in Fluo-4 monitoring of calcium levels in T. gondii in the present study. While artemisinin did not lead to higher resting levels of [Ca\(^{2+}\)]\(_{i}\), it did profoundly increase the periodicity and duration of calcium spikes in T. gondii. This behavior mimics the effects of thapsigargin on calcium oscillations by T. gondii, although thapsigargin was considerably more potent. The reason why the two compounds result in different profiles of calcium oscillations is uncertain but could result from differences in binding to the target and thus how they affect the cycling between the E1 and E2 conformations of the SERCA pump.

Previous studies have shown that during gliding motility, [Ca\(^{2+}\)]\(_{i}\) levels in T. gondii undergo periodic oscillations that are dramatically dampened during cell invasion (27). Calcium oscillations are a common phenomenon during fertilization, cell migration, and during the cell cycle in a variety of vertebrate systems from frogs to humans (2). The molecular basis of the oscillations seen in Toxoplasma is not known, although they suggest a simple two-component circuit consisting of a calcium release channel and a reuptake pump (SERCA). The source for the increase in cytoplasmic calcium is from an intracellular pool, since the periodicity and amplitude of calcium oscillations were not affected by removal of calcium from the medium. Calcium release channels have not yet been characterized in T. gondii, or for that matter in yeast, protozoa, or plants, and these organisms do not contain conserved calcium release channels typical of animal cells (36, 37). The control of calcium homeostasis is likely to be complex since T. gondii also contains several other P-type Ca\(^{2+}\) ATPases (36), as well as other cation exchangers (http://ToxoDB.org).

Artemisinin and its derivatives have been used widely as a therapy for malaria, owing to their extremely potent inhibition of the parasite (18). This activity may be due to inhibition of the parasite SERCA as demonstrated by expression studies in Xenopus (12). In these heterologous systems, artemisinins are highly selective for malaria SERCA versus mammalian enzymes, presumably due to molecular differences in the binding site within the calcium channel of SERCA (47). Toxoplasma is also much less sensitive to artemisinin than malaria (19, 20), although newer variants such as artemisone are considerably more potent against both organisms (18, 35). Interestingly, another plant product, ryanodine, also disrupts calcium homeostasis in T. gondii (26); however, its target is calcium release channels in the ER rather than the reuptake pump SERCA. Because these agents disrupt calcium homeostasis at opposing points (i.e., release versus uptake), their collective action might be expected to be synergistic. Collectively, our findings indicate an important role for calcium regulation in the Apicomplexa and support the idea that calcium pumps and channels are important potential drug targets in parasites.

ACKNOWLEDGMENTS

We are grateful to Sanjeev Krishna and Silvia Moreno for helpful comments, Kristen Hagar for GFP-HDEL, and Julie Nawas for expert technical assistance. Preliminary genomic DNA sequence data were provided by The Institute for Genomic Research, the Wellcome Trust Sanger Institute, Washington University, and the University of Pennsylvania.

This study was supported by grants from the NIH (AI067051) (L.D.S.) and the Ucharr Foundation (K.N.).
