Abstract The Ising chain with kinetic constraints provides many examples of totally irreversible zero-temperature dynamics leading to metastability with an exponentially large number of attractors. In most cases, the constrained zero-temperature dynamics can be mapped onto a model of random sequential adsorption. We provide a brief didactic review, based on the example of the constrained Glauber–Ising chain, of the exact results on the dynamics of these models and on their attractors that have been obtained by means of the above mapping. The Riviera model introduced recently by Puljiz et al. behaves similarly to the kinetically constrained Ising chains. This totally irreversible deposition model however does not enjoy the shielding property characterizing models of random sequential adsorption. It can therefore neither be mapped onto such a model nor (in all likelihood) be solved by analytical means. We present a range of novel results on the attractors of the Riviera model, obtained through an exhaustive enumeration for smaller systems and of extensive simulations for larger ones, and put these results into perspective with the exact ones which are available for kinetically constrained Ising chains.

1 Introduction

The slow nonequilibrium dynamics of a broad variety of systems, including structural glasses, spin glasses, and granular media, has often been modeled in terms of the motion of a particle in a multidimensional energy landscape with a great many valleys separated by barriers [1]. In mean-field models, barrier heights diverge in the thermodynamic limit, and so valleys become truly metastable states [2–4]. For finite-dimensional systems with short-range interactions, barrier heights and valley lifetimes remain finite at any finite temperature, so that metastability becomes a matter of time scales [5–10].

Zero-temperature dynamics may also lead to metastability, in the broad sense that the system does not reach its ground state. Focusing for definiteness our attention onto spin models on finite-dimensional lattices, zero-temperature dynamics is known to lead to metastability in several instances. The two-dimensional ferromagnetic Ising model under zero-temperature Glauber dynamics may end in configurations with one or more frozen-in stripes [11, 12], whose statistics has been described via crossing probabilities in critical percolation [13, 14]. On higher-dimensional lattices, the pattern of possible attractors is richer, including configurations with stochastic blinkers, i.e., clusters of spins that flip forever [11, 15]. The ferromagnetic spin chain under Glauber dynamics [16] reaches its ground state according to the coarsening paradigm [17], whereas zero-temperature Kawasaki dynamics yields metastability, in the sense that the energy of the blocked (or jammed) configurations reached by the dynamics is extensively above the ground-state energy [18, 19]. Spin chains endowed with zero-temperature single-spin-flip dynamics may also manifest metastability, at least in the following in two instances: In the presence of random ferromagnetic couplings, the spin chain has an exponentially large number of metastable configurations [20, 21]; On the other hand, preventing energy-preserving spin flips, and more generally imposing kinetic constraints, often leads to metastability. The latter situation is considered in detail below.

Kinetically constrained models have been introduced as the simplest systems of all exhibiting aging and many other features of the phenomenology of glassy dynamics [22]. For a broad range of one-dimensional kinetically constrained Ising models, zero-temperature dynamics
The kinetically constrained Ising chain

2.1 Generalities

The reduced Hamiltonian of the ferromagnetic Ising chain reads

$$\mathcal{H} = - \sum_n \sigma_n \sigma_{n+1},$$

(2)

where $\sigma_n = \pm 1$ are classical Ising spins living on the sites of a formally infinite chain.

To set the stage, the Ising chain is endowed with single-spin-flip dynamics, where each spin is flipped in continuous time at a rate $w(\delta H)$ depending only on the energy difference caused by the flip,

$$\delta H = 2\sigma_n(\sigma_{n-1} + \sigma_{n+1}) \in \{-4, 0, +4\}.$$ 

(3)

in particular that the Edwards hypothesis is in general not exactly valid for one-dimensional kinetically constrained models.

The goal of the present paper is to revisit the theory of one-dimensional spin models with kinetic constraints from a didactic viewpoint, and to use this body of knowledge to shed some new light onto the Riviera model [50]. The setup of this paper is as follows: In Sect. 2 we consider in detail the prototypical example of the kinetically constrained Ising chain, which can be mapped onto Flory’s dimer deposition model. We successively review the various a priori statistical ensembles of attractors (Sect. 2.2) and the exact results that can be derived on the dynamics of the model and on the statistics of its attractors (Sect. 2.3). Section 3 is devoted to the Riviera model. The latter model is a one-dimensional variant, introduced recently by Puljiz et al. [50], of a two-dimensional irreversible deposition model introduced earlier by the same authors [51, 52]. Houses are built sequentially on an infinite array of predrawn plots along a beach, with the constraint that every house should enjoy the sunlight from at least one of the side directions. In other words, at least one of the two neighboring plots of each house should remain forever unbuilt. The strand is initially empty. New houses are successively introduced until a blocked configuration is reached. The above dynamical rule couples both neighboring sites of any occupied one. The Riviera model therefore does not enjoy the shielding property. The ensuing lack of exact solvability has observable consequences, including the exponential decay of the connected occupation correlation.

We shall first consider the various a priori statistical ensembles of attractors (Sect. 3.2), and then present two kinds of results on the statistics of attractors, namely exact results obtained by enumeration on small systems (Sect. 3.3), and numerical results in the thermodynamic limit of very large systems (Sect. 3.4). Section 4 contains a discussion of our main findings.
Imposing detailed balance at inverse temperature $\beta$ gives one single relation between the three rates, namely

$$w(+4) = e^{-4\beta} w(-4). \quad (4)$$

At zero temperature, we have $w(+4) = 0$, expressing that spin flips that would increase the energy are suppressed. Choosing time units such that $w(-4) = 1$, zero-temperature dynamics is therefore entirely characterized by the rate $w(0)$ of energy-conserving flips. For generic values of the latter rate, the model exhibits coarsening \([17]\). This is in particular the case for the historical example of Glauber dynamics \([16]\), corresponding to $w(0) = 1/2$. The typical size of ferromagnetically ordered domains grows asymptotically as $L(t) \sim \sqrt{t}$, and so the energy density above the ground-state energy falls off as $1/\sqrt{t}$. On a large but finite system of $N$ spins, the coarsening phase is interrupted at a crossover time scaling as $t \sim N^2$, beyond which the system converges toward one of its ground states.

Energy-conserving flips are suppressed for the particular choice $w(0) = 0$. The descent dynamics thus obtained defines the kinetically constrained Ising chain. The only possible flips are those involving isolated spins:

$$--- \rightarrow +++, \quad +++ \rightarrow --. \quad (5)$$

Isolated spins therefore flip once during their whole history, whereas other spins never flip. This is one of the simplest kinetically constrained models and has been investigated at length in \([31-36]\). The main outcomes of these works will be reviewed in this section.

The descent dynamics of the constrained Ising chain can be recast as follows: Consider the dual lattice, where original bonds are mapped onto dual sites, and encode satisfied (resp. unsatisfied) bonds as occupied (resp. empty) dual sites:

$$\bullet: \quad \tau_n = \sigma_n \sigma_{n+1} = +1, \quad \circ: \quad \tau_n = \sigma_n \sigma_{n+1} = -1, \quad (6)$$

so that the Hamiltonian (2) reads

$$\mathcal{H} = -\sum_n \tau_n. \quad (7)$$

The spin flips (5) translate to

$$\circ\circ \rightarrow \bullet\bullet. \quad (8)$$

The constrained dynamics is thus mapped onto the dimer deposition model. The latter model, which was first solved by Flory \([48]\), is the simplest among all models in the RSA class. As shown in Fig. 1, attractors of the constrained Ising chain, where there are no isolated spins, are in one-to-one correspondence with blocked configurations of the dimer deposition model on the dual lattice, where empty sites are isolated. There are monomers, i.e., isolated occupied dual sites, because a generic initial configuration of the Ising chain does not correspond to an initially empty dual lattice \([31]\).

The energy density $E$ of the ferromagnetic Ising chain is related to the particle density $\rho$ of the dimer model as

$$E = 1 - 2\rho. \quad (9)$$

We shall focus our attention on the two-point energy correlation function, which is invariant under translations in the formally infinite system under consideration, namely

$$C_n = \langle \tau_0 \tau_n \rangle. \quad (10)$$

### 2.2 Statistical ensembles of attractors

In terms of the dimer deposition model, blocked configurations are those where all empty sites are isolated (Fig. 1). The statistical ensemble where all attractors are equally probable, according to a flat Edwards measure, is referred to as the full a priori ensemble, whereas the ensemble consisting of all attractors with fixed energy density $E$ with equal weights is the microcanonical a priori ensemble.

#### 2.2.1 Transfer-matrix formalism

As usual in statistical physics, instead of considering the microcanonical ensemble at fixed energy density $E$, it is advantageous to introduce the canonical ensemble defined by introducing an effective inverse temperature $\beta$, either positive or negative, conjugate to the Hamiltonian $\mathcal{H}$. Let us consider for a while a finite chain of $N$ sites, with prescribed boundary conditions, and introduce the partition function

$$Z_N = \sum_\mathcal{C} e^{-\beta \mathcal{H}(\mathcal{C})}, \quad (11)$$

where the sum runs over all blocked configurations $\mathcal{C}$ of the system of $N$ sites. The partial partition functions $Z_N^+\mathcal{C}$ and $Z_N^-\mathcal{C}$, defined by assigning fixed values to the occupation of the rightmost site, obey linear recursions...
of the form
\[(Z^*_{N+1}) = T(Z^*_{N}) ,\]
with prescribed initial values. The above relations involve the $2 \times 2$ transfer matrix
\[T = \left( \begin{array}{cc} e^\beta & e^\beta \\ e^{-\beta} & 0 \end{array} \right).\]
The eigenvalues of $T$ read
\[\lambda_\pm = \frac{1}{2} \left( e^\beta \pm \sqrt{4+e^{2\beta}} \right).\]
An associated biorthogonal set of left and right eigenvectors, such that
\[L_\pm \cdot R_\mp = 1, \quad L_\pm \cdot R_\pm = 0,\]
reads
\[L_\pm = \frac{\lambda_\pm e^\beta}{\lambda_\pm^2 + 1}, \quad R_\pm = \left( \begin{array}{c} \lambda_\mp e^{-\beta} \\ -\lambda_\pm^2 + 1 \end{array} \right).\]

2.2.2 Configurational entropy

The configurational entropy $S(E)$ introduced in (1) can be derived from the transfer-matrix formalism as follows: In the thermodynamic limit of a very large system size $N$, irrespective of boundary conditions, we have
\[Z_N \approx \int N(E) e^{-\beta NE} dE \sim \int e^{N(S(E) - \beta E)} dE \sim e^{N \ln \lambda_+(\beta)}.\]
We thus find that $S(E)$ is the Legendre transform of $\ln \lambda_+(\beta)$, i.e.,
\[S(E) = \ln \lambda_+(\beta) + \beta E,\]
with
\[\beta = \frac{dS}{dE}, \quad E = -\frac{d \ln \lambda_+}{d \beta}.\]
The above relations are germane to the usual thermodynamic ones between internal energy $E$ and free energy $F = E - TS$. Using (14), we obtain the expressions
\[E = -\frac{e^\beta}{\sqrt{4 + e^{2\beta}}}, \quad e^\beta = -\frac{2E}{\sqrt{1 - E^2}}.\]

and
\[S(E) = \frac{1}{2} (1 - E) \ln(1 - E) - \frac{1}{2} (1 + E) \ln(1 + E) + E \ln(-2E).\]
The configurational entropy $S(E)$ is plotted against the energy density $E$ in Fig. 2. It vanishes at both endpoints $E_{\text{min}} = -1$ and $E_{\text{max}} = 0$. Its maximum, corresponding to $\beta = 0$, namely
\[S_* = \ln \frac{\sqrt{5} + 1}{2} \approx 0.481212,\]
is reached for
\[E_* = -\frac{\sqrt{5}}{5} \approx -0.447214.\]
The above number is therefore the a priori most probable value of the energy density of an attractor of the Ising chain.

Another interpretation of the configurational entropy $S(E)$ is as follows: the a priori probability $P(E)$ of observing in the full statistical ensemble a blocked configuration with an atypical energy density $E \neq E_*$ is given by a large-deviation formula of the form
\[P(E) \sim \exp(-N \Sigma(E)),\]
where the a priori large-deviation function reads
\[\Sigma(E) = S_* - S(E).\]
This quantity is positive and vanishes quadratically in the vicinity of $E = E_*$. 

![Fig. 2](image-url) Configurational entropy $S(E)$ of the constrained Ising chain, as given in (21), against energy density $E$ of attractors (blocked configurations). Vertical dashed line: a priori energy density $E_*$ yielding the maximum configurational entropy $S_*$ (see (22), (23))
2.2.3 Correlation function

The expression \( C_{n, \text{mic}} \) of the two-point correlation introduced in (10) in the microcanonical a priori ensemble at fixed energy density \( E \) can also be derived from the transfer-matrix formalism. We have for \( n \geq 0 \) that

\[
C_{n, \text{mic}} = \lim_{M,N \to \infty} \frac{\text{tr} T^n E T^N}{\text{tr} T^{n+N}},
\]

i.e.,

\[
C_{n, \text{mic}} = \frac{L_+ \cdot E T^n E R_+}{\lambda_+^n} = (L_+ \cdot ER_+)^2 + (L_+ \cdot ER_-)(L_- \cdot ER_+) \left( \frac{\lambda_-}{\lambda_+} \right)^n.
\]

According to the equivalence between statistical ensembles, the transfer matrix \( T \), its largest eigenvalue \( \lambda_+ \), and the associated eigenvectors \( L_+ \) and \( R_+ \) are evaluated at the effective inverse temperature \( \beta \) related to the energy density \( E \) by (20). The diagonal matrix

\[
E = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}
\]

is the energy operator.

Using (14), (15), (16), as well as

\[
L_+ \cdot ER_\pm = \pm E, \quad L_\pm \cdot ER_\mp = 1 \pm E,
\]

we are left with the simple result

\[
C_{n, \text{mic}} = E^2 + (1 - E^2) \left( \frac{1 + E}{1 - E} \right)^n.
\]

The disconnected part of the above correlation is the square of the energy density \( E \), as should be. The connected part exhibits exponentially damped oscillations.

2.3 Exact results on dynamics and attractors

In this section we review, on the example of the constrained Ising chain whose dynamics can be mapped onto the dimer deposition model [31–36], the approach yielding exact analytical results on the dynamics and the attractors of RSA models in one dimension (see [45–47] for reviews).

Consider a factorized initial state where each variable \( \tau_n \) is chosen at random as

\[
\tau_n = -1 (\circ) \text{ with prob. } p, \quad \tau_n = +1 (\bullet) \text{ with prob. } 1 - p,
\]

so that the energy density of the Ising chain and the particle density of the dimer model read

\[
E(0) = E_0 = 2p - 1, \quad \rho(0) = \rho_0 = 1 - p.
\]

In particular, \( p = 1 \) corresponds to the dimer system’s being initially empty, whereas \( p = 1/2 \) corresponds to an infinite-temperature initial state for the Ising chain.

2.3.1 Energy density

The temporal evolution of thermodynamic quantities such as the energy density \( E(t) \) can be derived by analytical means by using the shielding property of one-dimensional RSA and germane problems, implying that the densities of empty intervals obey closed evolution equations. In terms of the dimer deposition model, let

\[
p_\ell(t) = \text{Prob} (\circ \cdots \circ \bullet) \quad (\ell)
\]

denote the density per unit length at time \( t \) of intervals consisting of exactly \( \ell \) consecutive empty sites, with \( \ell \geq 1 \), so that we have

\[
E(t) = 1 - 2\rho(t), \quad \rho(t) = 1 - \sum_{\ell \geq 1} p_\ell(t).
\]

The probabilities \( p_\ell(t) \) obey evolution equations that can be derived as follows. Clusters of length \( \ell = 1 \) are inactive, whereas a new dimer can be deposited at \( (\ell - 1) \) places on a cluster of length \( \ell \geq 2 \). We thus arrive to the coupled linear differential equations

\[
\frac{dp_\ell(t)}{dt} = -(\ell - 1)p_\ell(t) + 2 \sum_{k \geq \ell + 2} p_k(t)
\]

for \( \ell \geq 1 \), with initial condition

\[
p_\ell(0) = (1 - p)^2 p^\ell.
\]

Inserting an ansatz of the form \( p_\ell(t) = a(t) z(t)^\ell \) into (35) yields two differential equations for \( z(t) \) and \( a(t) \). We thus obtain

\[
p_\ell(t) = (1 - pe^{-t})^2 \exp(2p(e^{-t} - 1)) p^\ell e^{-(\ell - 1)t},
\]

and so

\[
E(t) = 2p \exp(2p(e^{-t} - 1)) - 1, \quad \rho(t) = 1 - p \exp(2p(e^{-t} - 1)).
\]

In the limit of infinitely long times, only inactive intervals of length \( \ell = 1 \) survive, as should be. Their limiting density reads

\[
p_1(t \to \infty) = pe^{-2p},
\]

\[\circ\] Springer
and so

\[ E_\infty = 2pe^{-2p} - 1, \quad \rho_\infty = 1 - pe^{-2p} \tag{40} \]

are respectively the final energy and particle densities in the blocked configurations.

For an initially empty system \((p = 1)\), the final density (or coverage) of the dimer deposition model reads

\[ \rho_\infty = 1 - e^{-2} \approx 0.864664. \tag{41} \]

This is the celebrated result of Flory \[48\].

Using \((32)\) and \((40)\), the final energy density \(E_\infty\) of the constrained Ising chain can be expressed as a function of its initial energy density \(E_0\), namely

\[ E_\infty = (E_0 + 1)e^{-E_0} - 1. \tag{42} \]

The final energy \(E_\infty\) is plotted against \(E_0\) in Fig. 3. It is significantly lower than the a priori value \((23)\), and lower than \(E_0\), as should be. Furthermore, it exhibits a nonmonotonic dependence on \(E_0\). Near the ground-state energy \((E_0 \to -1)\), we have \(E_\infty - E_0 \approx (E_0 + 1)^2\). The final energy increases to the maximal value

\[ E_\infty = e^{-1} - 1 \approx -0.632120 \tag{43} \]

for \(E_0 = 0\), i.e., an infinite-temperature initial state, and then decreases to the value

\[ E_\infty = 2e^{-2} - 1 \approx -0.729329 \tag{44} \]

for \(E_0 = 1\), i.e., an antiferromagnetically ordered initial state.

### 2.3.2 Energy correlation function

The temporal evolution of the two-point correlation introduced in \((10)\) can also be obtained by using the shielding property. The derivation involves the following one-cluster and two-cluster functions:

\[ c_n(t) = \text{Prob}(\circ \cdots \circ), \]

\[ d_{m,k,n}(t) = \text{Prob}(\circ \cdots \circ \circ \cdots \circ \circ \cdots \circ), \tag{45} \]

where the contents of the middle interval of length \(k\) is unspecified. The above functions obey the coupled linear equations

\[ \frac{dc_n(t)}{dt} = -(n - 1)c_n(t) - 2c_{n+1}(t), \]

\[ \frac{dd_{m,k,n}(t)}{dt} = -(m + n - 2)d_{m,k,n}(t) \]

\[ - d_{m+1,k,n}(t) - d_{m,k,n+1}(t) \]

\[ - d_{m+1,k-1,n}(t) - d_{m,k-1,n+1}(t), \tag{46} \]

with appropriate initial and boundary conditions.

 Skipping details, we mention the expression of the final connected correlation \((n \geq 1)\) \[35\]:

\[ C_{n,\infty} - E_\infty^2 = 2pe^{-2p}\frac{(-2p)^n}{n!} - 4p^2e^{-2p}\sum_{m \geq n} \frac{(-2p)^m}{m!}. \tag{47} \]

This result exhibits the generic features of connected correlations in the RSA model already mentioned in Sect. 1 \[45-47\], including oscillations and, more importantly, an inverse factorial fall-off. This peculiar kind of superexponential decay seems to have been evidenced first in \[53\] (see \[54, 55\] for alternative derivations).

Figure 4 shows a comparison between the final connected correlation \(C_{n,\infty} - E_\infty^2\), given by \((47)\), and its counterpart \(C_{n,\text{mic}} - E_\infty^2\) in the a priori microcanonical ensemble at fixed energy \(E\) (see \((30)\)). For the comparison to be fair, the exact final energy \(E_\infty\) has been used to define the a priori ensemble. Data corresponding to an infinite-temperature initial state, i.e., \(p = 1/2\) or \(E_0 = 0\), so that \(E_\infty\) is given by \((43)\), are plotted on a logarithmic scale against distance \(n\). The microcanonical ensemble correctly predicts \(C_{0,\text{mic}} = C_{0,\infty} = 1\), by construction, as well as \(C_{1,\text{mic}} = C_{1,\infty} = -2E_\infty - 1\). The two datasets cross each other between distances \(5\) and \(6\). The superexponential decay of the exact correlations is clearly visible.

### 2.3.3 Dynamical entropy

The above method can be further extended to derive an exact expression for the full dynamical entropy function \(\Sigma_\infty(E)\), such that the probability \(P_{\text{mic}}(E)\) of observing a final blocked configuration with an atypical energy density \(E \neq E_\infty\) is given by a large-deviation formula
of the form

\[ P_\infty(E) \sim \exp(-N\Sigma_\infty(E)). \] (48)

The calculations involved in the derivation of dynamical large-deviation functions in RSA models [35, 36, 56] are more intricate than those described in Sects. 2.3.1 (energy density) and 2.3.2 (energy correlation).

Skipping all the details, we mention that the dynamical entropy \( \Sigma \) is given by the following parametric form [35]:

\[
\Sigma_\infty = \ln z + \frac{(1 + (2p - 1)z)^2 - (1 - z)^2 e^{4pz}}{4pz^2 e^{2pz} (2(1 - p) + (2p - 1)z)} \\
\times \ln \frac{1 + (2p - 1)z + (1 - z)e^{2pz}}{1 + (2p - 1)z - (1 - z)e^{2pz}},
\]

\[
E = \frac{(1 + (2p - 1)z)^2 - (1 - z)^2 e^{4pz}}{2pz^2 e^{2pz} (2(1 - p) + (2p - 1)z)} - 1, \] (49)

where the parameter \( z \) runs between zero and a positive maximal value \( z_c \), such that

\[ 1 + (2p - 1)z_c + (1 - z_c)e^{2pz_c} = 0. \] (50)

The dynamical entropy \( \Sigma_\infty(E) \) is positive, vanishes quadratically in the vicinity of \( E = E_\infty \), and has finite limits at both endpoints, namely

\[
\Sigma_\infty(-1) = \ln z_c, \]

\[
\Sigma_\infty(0) = -\frac{1}{2} \ln(p(1 - p)). \] (51)

Figure 5 shows a comparison between the dynamical entropy \( \Sigma_\infty(E) \) given in (49), for \( p = 1/2 \), corresponding to \( E_0 = 0 \), i.e., an infinite-temperature initial state, and the a priori large-deviation function \( \Sigma(E) \), given in (25). Both quantities are plotted against the energy density \( E \).

3 The Riviera model

3.1 Definition

The Riviera model is the one-dimensional variant introduced recently by Puljiz et al. [50] of a two-dimensional irreversible deposition model introduced earlier by the same authors [51, 52]. Houses are sequentially built on a system of length 40, comprising 25 houses (filled symbols) and 15 empty plots (empty symbols).
onto an RSA model, nor (in all likelihood) be solved by analytical means. Hereafter, we first investigate the a priori statistical ensembles of blocked configurations, and then present two kinds of results on the statistics of attractors, namely exact results obtained by enumeration on small systems, and numerical results in the thermodynamic limit of very large systems.

The basic dynamical variable is the occupation \( \eta_n \) of plot number \( n \):

\[
\bullet: \quad \eta_n = 1, \\
\circ: \quad \eta_n = 0. 
\]

We shall be mostly interested in the final particle density (or coverage) of the model when it has reached one of the many attractors at its disposal,

\[ \rho_\infty = \langle \eta_0 \rangle_\infty, \]

and in the final occupation correlation

\[ C_{n,\infty} = \langle \eta_n \eta_0 \rangle_\infty. \]

### 3.2 Statistical ensembles of attractors

The attractors of the Riviera model are the blocked configurations in which no new house can be built. They admit a local description in terms of two (possibly overlapping) local patterns:

\[
\bullet\bullet\bullet\bullet, \quad \bullet\bullet\bullet. 
\]

In line with Sect. 2.2, the statistical ensemble where all attractors are equally probable, irrespective of their particle density \( \rho \), is referred to as the full a priori ensemble, whereas the ensemble consisting of all attractors with fixed density \( \rho \) is the microcanonical a priori ensemble.

#### 3.2.1 Transfer-matrix formalism

Along the lines of Sect. 2.2, we introduce the Hamiltonian

\[ H = - \sum_n \eta_n, \]

as well as the canonical ensemble defined by introducing an effective inverse temperature \( \beta \) conjugate to \( H \).

The structure of the local patterns (55) leads us to introduce six partial partition functions, defined by assigning to the occupations of the three rightmost sites their six different permitted values. These obey the linear recursion

\[
\begin{pmatrix}
Z^\circ \circ \circ \\
Z^\circ \circ \circ +1 \\
Z^\circ \bullet \circ +1 \\
Z^\circ \bullet \circ +1 \\
Z^\bullet \circ \bullet +1 \\
Z^\bullet \circ \bullet +1 \\
\end{pmatrix}
= \mathbf{T}
\begin{pmatrix}
Z^\circ \circ \circ \\
Z^\circ \circ \circ +1 \\
Z^\circ \bullet \circ +1 \\
Z^\circ \bullet \circ +1 \\
Z^\bullet \circ \bullet +1 \\
Z^\bullet \circ \bullet +1 \\
\end{pmatrix}
\]

involving the \( 6 \times 6 \) transfer matrix

\[
\mathbf{T} = \begin{pmatrix}
0 & 0 & 0 & x & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 \\
x & 0 & 0 & x & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 \\
0 & x & 0 & 0 & 0 & x \\
0 & 0 & 1 & 0 & 0 & 0 \\
\end{pmatrix},
\]

with the notation

\[ x = e^{-\beta}. \]

The effective inverse temperature \( \beta \) may be either positive or negative, so that the parameter \( x \) may assume any real positive value. An equivalent transfer-matrix formalism was investigated in [50].

The characteristic equation of the transfer matrix \( \mathbf{T} \) reads

\[ \lambda^6 - x\lambda^4 - x^2(\lambda^3 + \lambda^2) + x^3 = 0. \]

Quite remarkably, the above equation turns out to admit the rational parameterization

\[
x = \frac{(u - 1)^4(u + 1)^2}{u^3},
\]

\[
\lambda = \frac{(u - 1)^2(u + 1)}{u}. 
\]

For any fixed \( x \), (61) yields six values of \( u \), and (62) yields the corresponding six eigenvalues \( \lambda_a \) of \( \mathbf{T} \). We denote by \( \mathbf{L}_a \) and \( \mathbf{R}_a \) the left and right eigenvectors associated with \( \lambda_a \), normalized so as to have \( \mathbf{L}_a \cdot \mathbf{R}_a = \delta_{ab} \).

The parameterization (61), (62) implies the following symmetry: Changing \( u \) into \( 1/u \) leaves \( x \) invariant and changes \( \lambda \) into \( x/\lambda \). Therefore, for any fixed \( x \), if \( \lambda \) is an eigenvalue of \( \mathbf{T} \), corresponding to the parameter \( u \), \( x/\lambda \) is another eigenvalue, corresponding to the parameter \( 1/u \). The transfer matrix \( \mathbf{T} \) has degenerate eigenvalues in two cases: \( x = 0 \), where the six eigenvalues collapse to the origin, and

\[ x_c = \frac{256}{27} \approx 9.481481, \]

where \( \mathbf{T} \) has a pair of twice-degenerate complex eigenvalues. In the most relevant range \( x < x_c \), the structure
of the spectrum of $T$ is shown in Fig. 7. The largest eigenvalue $\lambda_1$ and the smallest one $\lambda_2 = x/\lambda_1$ are real positive, whereas the four other eigenvalues $\lambda_3, \ldots, \lambda_6$ form two complex conjugate pairs, with negative real parts and common modulus $\sqrt{x}$. For $x > x_c$, one pair of complex eigenvalues have modulus less than $\sqrt{x}$, whereas the other pair have modulus greater than $\sqrt{x}$.

### 3.2.2 Statistics of finite systems

Before we investigate the configurational entropy and correlations in the thermodynamic limit, let us focus our attention on finite systems.

The number $N_{N,M}$ of distinct blocked configurations comprising $M$ houses on a finite system of $N$ sites can be derived from the transfer-matrix formalism as follows: The partition function

$$Z_N(x) = \sum_{M} N_{N,M} x^M$$

is given by the linear combination corresponding to open boundary conditions at both ends of the partial partition functions obeying the recursion (57). Some algebra yields the expression

$$Z_N(x) = L_{\text{open}} T^N R_{\text{open}},$$

with

$$L_{\text{open}} = (0 0 1 0 1 1),$$
$$R_{\text{open}} = (0 0 0 0 0 1)^T,$$

where the superscript $T$ denotes transposition. The total number of distinct blocked configurations on a system of size $N$ reads

$$N_N = \sum_{M} N_{N,M} = Z_N(1).$$

The partition functions $Z_N(x)$ and the numbers $N_N$ obey the linear recursions

$$Z_{N+6}(x) - x Z_{N+4}(x) - x^2 (Z_{N+3}(x) + Z_{N+2}(x)) + x^3 Z_N(x) = 0,$$

$$N_{N+6} - N_{N+4} - N_{N+3} - N_{N+2} + N_N = 0,$$

as a consequence of the characteristic equation (60).

An elegant presentation of the above results in terms of their generating series was given in [50]. With the present notations, we have

$$Z(x,y) = \sum_{M,N} N_{N,M} x^M y^N$$

$$= \sum_{N \geq 0} Z_N(x) y^N$$

$$= L_{\text{open}} (1 - y T)^{-1} R_{\text{open}}$$

$$= 1 + x y + x(x-1) y^2 + x^2 y^3 - x^3 y^5$$

$$= 1 - x^2 - x^2(y^3 + y^4) + x^3 y^6,$$

and

$$z(y) = \sum_{N \geq 0} N_N y^N$$

$$= Z(1,y)$$

$$= \frac{1 + y + y^3 - y^5}{1 - y^2 - y^4 + y^6}.$$

The above results were also put in perspective with several combinatorial problems in [50]. In particular, the numbers $N_N$ of blocked configurations count a class of permutations with strongly restricted displacements. They are listed in the OEIS under reference A080013 [57] (see also [58]).

Table 1 gives the expression of the partition function $Z_N(x)$ and the total number $N_N$ of blocked configurations for sizes $N$ up to 14. The last line means that, on a system of $N = 14$ sites, there are altogether 91 distinct blocked configurations, among which 50 have $M = 8$ houses, 40 have $M = 9$, and a single one has $M = 10$. The mean particle density $\rho_{N,*}$ in the a priori ensemble where all blocked configurations of the finite system of size $N$ are equally probable reads

$$\rho_{N,*} = \frac{1}{N Z_N} \left( \frac{dZ_N}{dx} \right)_{x=1}.$$
Table 1 Partition functions $Z_N(x)$ of finite systems of $N$ sites, for $N$ up to 14. The quantity $N_N = Z_N(1)$ is the total number of distinct blocked configurations on a system of size $N$.

| $N$ | $Z_N(x)$ | $N_N$ |
|-----|----------|-------|
| 0   | 1        | 1     |
| 1   | $x$      | 1     |
| 2   | $x^2$    | 1     |
| 3   | $3x^2$   | 3     |
| 4   | $x^2 + 2x^3$ | 3     |
| 5   | $3x^3 + x^4$ | 4     |
| 6   | $6x^4$   | 6     |
| 7   | $6x^4 + 3x^5$ | 9     |
| 8   | $x^4 + 10x^5 + x^6$ | 12   |
| 9   | $6x^5 + 10x^6$ | 16   |
| 10  | $20x^6 + 4x^7$ | 24   |
| 11  | $10x^6 + 22x^7 + x^8$ | 33   |
| 12  | $x^6 + 30x^7 + 15x^8$ | 46   |
| 13  | $10x^7 + 49x^8 + 5x^9$ | 64   |
| 14  | $50x^8 + 40x^9 + x^{10}$ | 91   |

3.2.3 Configurational entropy

The configurational entropy $S(\rho)$ is given by (18), (19), up to the replacement of the energy density $E$ by the particle density $\rho$, and of $\lambda + \mu$ by the largest eigenvalue $\lambda_1$ of $T$. With the parameterization (61), (62), $\lambda_1$ is reached for $u$ real in the range $1 < u < +\infty$. We thus obtain the following parametric representation of the configurational entropy:

$$\rho = \frac{2u^2 + u + 1}{D},$$

$$S = \frac{A}{D},$$

$$A = u(3u + 1) \ln u - (u^2 - 1) \ln((u - 1)^2(u + 1)),$$

$$D = 3u^2 + 2u + 3.$$  \hfill (73)

$$S, \approx 0.337377,$$ \hfill (77)

The above value of $\rho_*$ represents the most probable particle density in the full a priori statistical ensemble.

3.2.4 Correlation function

The expression $C_n,_{\text{mic}}$ of the occupation correlation introduced in (54) in the microcanonical a priori ensemble at fixed density $\rho$ can be derived from the transfer-matrix formalism along the lines of Sect. 2.2.

In analogy with (27), we have for $n \geq 0$ that

$$C_n,_{\text{mic}} = \frac{B_n}{\lambda_1^n},$$

with

$$B_n = L_1 \cdot YT^n YR_1$$

$$= \sum_{a=1}^{6} (L_1 \cdot YR_a)(L_a \cdot YR_1)\lambda_1^n.$$ \hfill (81)

Here again, the transfer matrix $T$ and its eigenvalues and eigenvectors are evaluated at the effective inverse temperature $\beta$ related to the density $\rho$ by (59), (61), (73). The diagonal matrix

$$Y = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0
\end{pmatrix}$$
is the occupation operator. We have consistently \( L_1 \cdot \text{YR}_1 = \rho \), so that the term with \( a = 1 \) in (81) yields the expected disconnected component of the correlation, namely \( \rho^2 \).

The expression (80) for the numerators \( B_n \) implies that they obey the same linear recursion as the partition functions \( Z_N(x) \) (see (68)), i.e.,

\[
B_{n+6} - xB_{n+4} - x^2(B_{n+3} + B_{n+2}) + x^3B_n = 0. \tag{83}
\]

With the parameterization (61), (62), the recursion (83) translates to a recursion relation for the microcanonical correlations \( C_{n,\text{mic}} \) themselves:

\[
u^3C_{n+6,\text{mic}} - \nu^2C_{n+4,\text{mic}} - (\nu - 1)^2(\nu + 1)C_{n+3,\text{mic}} - \nu C_{n+2,\text{mic}}+ C_{n,\text{mic}} = 0. \tag{84}
\]

The above recursion allows one to determine recursively the correlations at all distances from the following first six values:

\[
C_{0,\text{mic}} = \frac{2u^2 + u + 1}{D}, \quad C_{1,\text{mic}} = \frac{u^2}{D}, \quad C_{2,\text{mic}} = \frac{u(u + 1)}{D}, \quad C_{3,\text{mic}} = \frac{2u^2 - 1}{D}, \quad C_{4,\text{mic}} = \frac{u^3 + 2u + 1}{uD}, \quad C_{5,\text{mic}} = \frac{(u^2 + u - 1)^2}{u^2D}, \tag{85}
\]

which can be derived from (79), (80) using computer algebra. The denominator \( D \) is given in (76).

The numerators of the first four correlations in (85) are quadratic in \( u \). These quantities therefore obey two linear identities, which can be written as

\[
C_2 = 3\rho - 2C_1 - 1, \quad C_3 = 2\rho + C_1 - 1. \tag{86}
\]

All “mic” subscripts have been suppressed in the above equations for the following reason: these identities have been derived within the microcanonical framework, irrespective of the parameter \( u \), i.e., irrespective of the mean density \( \rho \). It will be shown below that these are constitutive identities, which ensue from the mere structure of the blocked configurations. In particular, the above identities hold for the final correlations \( C_{n,\infty} \).

The large-distance behavior of the connected correlation is dominated by the terms with \( a = 3, \ldots, 6 \) in (81), involving the four complex eigenvalues of \( \mathbf{T} \). The phases of the latter eigenvalues are generically not rationally related to \( \pi \). The connected correlations therefore exhibit everlasting quasiperiodic oscillations, whose hull falls off exponentially as

\[
C_{n,\text{mic}} - \rho^2 \sim e^{-\mu n}. \tag{87}
\]

For \( x < x_\text{c} \), the structure of the spectrum shown in Fig. 7 implies

\[
\mu = \ln \frac{\lambda_1}{\sqrt{x}} = \frac{1}{2} \ln u. \tag{88}
\]

### 3.3 Exact results on the attractors of finite systems

In the dynamics of the Riviera model, sites (i.e., plots of land) are visited in a random sequential order. The totally irreversible rules of the model ensure that a house may be built at a given site only at the first time this site is visited, whereas any subsequent visit is doomed to be sterile.

For an initially empty finite system of \( N \) sites, the attractor reached by a given realization of the process therefore only depends on the order in which the various sites are visited for the first time. It is advantageous to encode this ordering by a permutation \( \sigma \) of the \( N \) site labels \((i = 1, \ldots, N)\), such that site \( \sigma_1 \) is visited first, and so on, until site \( \sigma_N \) is visited last. There are \( N! \) distinct permutations, and therefore \( N! \) equally probable distinct realizations of the Riviera process. It is natural to define the dynamical weight \( W(C) \) of each attractor \( C \) as being the number of permutations for which the system ends up in the blocked configuration \( C \). An analogous approach based on uniform random permutations was already used in earlier work [59].

For moderate values of the system size \( N \), the \( N! \) permutations can be enumerated and the corresponding dynamics be run by a computer routine, yielding the dynamical weights of all attractors of the model, and therefore the exact values of all observables defined in terms of those attractors. In particular, the mean final particle density on a system of size \( N \) reads

\[
\rho_{N,\infty} = \frac{1}{N!} \sum_C W(C)M(C), \tag{89}
\]

where the sum runs over all blocked configurations \( C \) of size \( N \), \( W(C) \) is the dynamical weight of \( C \) defined above, and \( M(C) \) is the number of occupied sites (i.e., houses) in \( C \).

Table 2 gives the dynamical weights \( W(C) \) of all attractors of the Riviera model, as obtained via the above enumeration approach, ordered by increasing values of system size \( N \) and number \( M \) of occupied sites, for \( N \) up to 8. The numbers of attractors at fixed \( N \) and \( M \) agree with the expressions of the partition functions given in Table 1.

The exact rational values of the a priori densities \( \rho_{N,\infty} \), defined in (72) in terms of the partition functions \( Z_N \), and of the final densities \( \rho_{N,\infty} \), defined in (89)
Table 2 Dynamical weights $W(C)$ of all attractors of the Riviera model, ordered by increasing values of system size $N$ and number $M$ of occupied sites, for $N$ up to 8

The dynamical weights $W(C)$, are given in Table 3 and plotted against $1/N$ in Fig. 9 for system sizes $N$ up to 14, the largest system size for which the systematic enumeration approach has been carried out.

The complexity of the expressions of the final densities increases much faster than that of the a priori ones. This testifies to the nontriviality of the dynamics of the Riviera model. Except for the system sizes $N = 1, 2, 3, 6$, where all attractors have the same numbers of houses, respectively $M = 1, 2, 2, 4$, the final density $\rho_{N,\infty}$ is larger than the a priori one by a few percent. This means that the dynamics of the Riviera model affects the final densities.

Table 3 Exact rational values of the a priori densities $\rho_{N,*}$ defined in (72), and of the final densities $\rho_{N,\infty}$ defined in (89), for system sizes $N$ up to 14

![Fig. 9](image-url) Blue symbols: a priori densities $\rho_{N,*}$ defined in (72). Red symbols: final densities $\rho_{N,\infty}$ defined in (89). Data are taken from Table 3 and plotted against $1/N$, for sizes $N$ ranging from 4 to 14. Arrows: respective limits $\rho_{*}$ given in (78) and $\rho_{\infty}$ given in Table 4. Dashed lines: guides to the eye demonstrating the asymptotic $1/N$ convergence of both datasets.
model is able to reach on average slightly more compact configurations than a flat ensemble. We shall come back to this point in Sect. 4.

For very large system sizes, the a priori densities $\rho_{N,*}$ converge to the exactly known limit $\rho_*$ given in (78), whereas the final densities $\rho_{N,\infty}$ converge to the limit $\rho_\infty$, given in Table 4, which is only known through extensive numerical simulations. Figure 9 demonstrates that both datasets exhibit some irregular behavior for the smaller sizes, and smoothly converge to their respective limits as $1/N$.

### 3.4 Numerical results in the thermodynamic limit

We end our investigation of the attractors of the Riviera model by discussing the outcomes of extensive numerical simulations on systems of sizes $N = 100$ and 200, comprising a total of $3.10^{12}$ sites. We have measured the final occupation correlation $C_{n,\infty}$ for distances $n$ up to 13, beyond which the connected correlation is too small to be measured accurately.

Before we present numerical results, we wish to emphasize that the mean particle density and nearest-neighbor occupation correlation, i.e.,

$$ C_{0,\infty} = \rho_\infty, \quad C_{1,\infty}, $$

(90)

can serve as a basis to express the main local observables characterizing the blocked configurations. First of all, the two local densities and the four nearest-neighbor correlations read

$$ \langle \bullet \rangle_\infty = \rho_\infty, $$
$$ \langle \circ \rangle_\infty = 1 - \rho_\infty, $$
$$ \langle \bullet \bullet \rangle_\infty = C_{1,\infty}, $$
$$ \langle \bullet \circ \rangle_\infty = \langle \bullet \rangle_\infty - \rho_\infty - C_{1,\infty}, $$
$$ \langle \circ \circ \rangle_\infty = C_{1,\infty} - 2\rho_\infty + 1. $$

(91)

Using the above expressions, we can prove that the identities (86) are constitutive to the model, by using only the local structure of the blocked configurations, as given by the patterns (55), as well as their translational invariance. We have indeed

$$ C_{2,\infty} = \langle \bullet \bullet \rangle_\infty $$
$$ = \langle \bullet \circ \rangle_\infty - \langle \circ \circ \rangle_\infty $$
$$ = \langle \circ \rangle_\infty - \langle \circ \circ \rangle_\infty $$
$$ = 3\rho_\infty - 2C_{1,\infty} - 1, $$
$$ C_{3,\infty} = \langle \bullet \bullet \bullet \rangle_\infty + \langle \bullet \bullet \circ \rangle_\infty + \langle \bullet \circ \bullet \rangle_\infty $$
$$ = \langle \circ \rangle_\infty + 2\langle \bullet \circ \rangle_\infty $$
$$ = \langle \circ \rangle_\infty + 2(\langle \bullet \circ \rangle_\infty - \langle \bullet \circ \rangle_\infty) $$
$$ = 2\rho_\infty + C_{1,\infty} - 1. $$

(92)

### Table 4 Numerical values of the two basic observables introduced in (90) and of all local observables given in (91), (93), (94)

| $\rho_\infty$  | 0.600385 |
|----------------|-----------|
| $C_{1,\infty}$ | 0.237565  |
| $\langle \bullet \rangle_\infty$ | 0.600385 |
| $\langle \circ \rangle_\infty$ | 0.399615 |
| $\langle \bullet \bullet \rangle_\infty$ | 0.237565 |
| $\langle \bullet \circ \rangle_\infty$ | 0.362820 |
| $\langle \circ \circ \rangle_\infty$ | 0.036795 |
| $\rho_\infty(\bullet)$ | 0.125255 |
| $\rho_\infty(\bullet \bullet)$ | 0.237565 |
| $\rho_\infty(\circ)$ | 0.326025 |
| $\rho_\infty(\circ \circ)$ | 0.036795 |
| $\rho_\infty(\circ \circ)(\text{cl})$ | 0.362820 |

The densities $\rho_\infty(\bullet)$ and $\rho_\infty(\bullet \bullet)$ of clusters of one and two consecutive occupied sites (houses) and the densities $\rho_\infty(\circ)$ and $\rho_\infty(\circ \circ)$ of clusters of one and two consecutive empty sites read

$$ \rho_\infty(\bullet) = \rho_\infty - 2C_{1,\infty}, $$
$$ \rho_\infty(\bullet \bullet) = C_{1,\infty}, $$
$$ \rho_\infty(\circ) = 3\rho_\infty - 2C_{1,\infty} - 1, $$
$$ \rho_\infty(\circ \circ) = C_{1,\infty} - 2\rho_\infty + 1. $$

(93)

The total density of clusters of occupied (or empty) sites therefore reads

$$ \rho_\infty(\text{cl}) = \rho_\infty(\bullet) + \rho_\infty(\bullet \bullet) $$
$$ = \rho_\infty(\circ) + \rho_\infty(\circ \circ) $$
$$ = \langle \bullet \rangle_\infty + \langle \circ \rangle_\infty $$
$$ = \rho_\infty - C_{1,\infty}. $$

(94)

Table 4 gives the numerical values of the two basic observables introduced in (90), as well as those of the local observables given in (91), (93), (94). In these and subsequent numerical values, statistical errors are estimated to be on the order of $10^{-6}$, i.e., one unit in the last significant digit.

Let us turn to the comparison of numerical data with the predictions of the a priori ensembles. The final density $\rho_\infty \approx 0.600385$ (Table 4) is larger than the most probable density $\rho_* \approx 0.577203$ in the full a priori ensemble (see (78)) by a small but significant amount,

$$ \rho_\infty - \rho_* \approx 0.023182. $$

(95)

It is interesting to observe that $\rho_*$ is slightly below the middle of the range $[1/2, 2/3]$ of permitted densities, namely $\rho_{\text{mid}} = 7/12 \approx 0.583333$, whereas $\rho_\infty$ is slightly larger than $\rho_{\text{mid}}$. These inequalities are rather general.
Table 5 Numerical values of the final correlations $C_{n,\infty}$, exact microcanonical correlations $C_{n,\text{mic}}$, and differences $C_{n,\infty} - C_{n,\text{mic}}$, for distances $n = 1$, 2, and 3, where correlations obey the identities (86)

| $n$ | $C_{n,\infty}$ | $C_{n,\text{mic}}$ | $C_{n,\infty} - C_{n,\text{mic}}$ |
|-----|----------------|---------------------|----------------------------------|
| 1   | 0.237565       | 0.236440            | +0.001125                        |
| 2   | 0.326025       | 0.328275            | −0.002250                        |
| 3   | 0.438335       | 0.437210            | +0.001125                        |

We shall come back to this point in Sect. 4 (see (99) and Table 6).

The microcanonical a priori ensemble of blocked configurations whose mean density equals the final density $\rho_\infty$ corresponds to the following values of the parameters $u$ and $x$ (see (61), (73), (76)):

$$u_\infty \approx 2.574600, \quad x_\infty \approx 4.602640.$$  (96)

The small density difference (95) translates into a sizeable difference between $x_\infty$ and the value of $x$ maximizing the configurational entropy, i.e., $x_* = 1$ by construction. We nevertheless have $x_\infty < x_*$ (see (63)). The correlation $C_{n,\text{mic}}$ in the microcanonical ensemble at density $\rho_\infty$ can be readily obtained for all distances $n$ by inserting the value of $u_\infty$ given in (96) into the initial values (85) and the recursion (84).

Table 5 presents a comparison between the numerical values of the final correlations $C_{n,\infty}$ and the exact microcanonical ones $C_{n,\text{mic}}$ for distances $n = 1$, 2, and 3, where correlations obey the identities (86). The differences $C_{n,\infty} - C_{n,\text{mic}}$, given in the last column, are very small. More importantly, they are found to be proportional to $+1$, $-2$, and $+1$, in agreement with the identities (86). This parameter-free agreement to all significant digits provides a quantitative check of the accuracy of our numerical results.

Figure 10 shows a comparison between the final connected correlation $C_{n,\infty} - \rho_\infty^2$ (numerical values, red symbols) and its counterpart $C_{n,\text{mic}} - \rho_\infty^2$ in the microcanonical a priori ensemble at fixed density $\rho_\infty$ (exact values, blue symbols). Data are plotted on a logarithmic scale against distance $n$. Full (resp. empty) symbols denote positive (resp. negative) connected correlations. The blue dashed line has the exact slope (97). The red dashed with slope 0.81 is the outcome of a least-squares fit off roughly twice as fast, with an apparent decay rate

$$\mu_\infty \approx 0.81$$  (98)

(red dashed line). The observed period three in the signs of final connected correlations is probably a transient phenomenon with no intrinsic meaning.

4 Discussion

The goal of the present paper was twofold. We have given a concise review of the theory of one-dimensional spin models with kinetic constraints, exemplified by the case of the constrained Ising chain, and put this body of knowledge in perspective with a range of novel results on the Riviera model introduced recently by Puljiz et al. [50].

This work has evidenced that there are both significant analogies and differences between the one-dimensional kinetically constrained models whose fully irreversible zero-temperature dynamics can be mapped onto an RSA model, and the Riviera model, whose fully irreversible dynamics does not enjoy the characteristic shielding property of those RSA models. It is worth noticing that the bilateral avatar of the Riviera model, defined by the requirement that both neighboring plots of each house should remain forever unbuilt, amounts to a deposition model with excluded volume described in [45]. The latter model is equivalent to the dimer deposition model on the dual lattice. It therefore belongs to the above class of kinetically constrained models.
Table 6 Various characteristic densities for the Riviera model and four kinetically constrained Ising chains whose dynamics can be mapped onto an RSA model: $\rho_{\text{min}}$ and $\rho_{\text{max}}$ are the endpoints of the range of permitted densities, $\rho_{\text{mid}}$ is the midpoint of the latter range, $\rho_*$ is the most probable density in the full a priori statistical ensemble, $\rho_{\infty}$ is the final density of the attractors of the irreversible dynamics launched from a prescribed initial state, be it either empty or corresponding to $\rho$ of the latter range, $\rho_{\text{a}}$ is the most probable density in the full a priori statistical ensemble, $\rho_{\text{c}}$ and $\rho_{\text{e}}$ are the endpoints of the range of permitted densities, and $\rho_{\text{a}}$ is the most probable density in the full a priori statistical ensemble.

| Number | Model                  | $\rho_{\text{min}}$ | $\rho_{\text{max}}$ | $\rho_{\text{mid}}$ | $\rho_*$ | $\rho_{\infty}$ |
|--------|------------------------|----------------------|----------------------|----------------------|---------|-----------------|
| 1      | Riviera                | 0.5                  | 0.666666             | 0.583333             | 0.577203| 0.600385        |
| 2      | Dimers                 | 0.666666             | 1                    | 0.833333             | 0.822991| 0.864664        |
| 3      | Ising–Glauber          | 0.5                  | 1                    | 0.75                 | 0.723607| 0.816060        |
| 4      | Ising–Kawasaki         | 0.333333             | 1                    | 0.666666             | 0.618420| 0.637043        |
| 5      | Paramagnetic Ising     | 0.5                  | 1                    | 0.75                 | 0.723607| 0.696734        |

Among the common features shared by the Riviera model and the class of RSA models, we wish to under-line that the final particle density $\rho_{\infty}$, i.e., the particle density of the attractors reached by the dynamics, is slightly different from the most probable density $\rho_*$ in the full a priori ensemble of blocked configurations. One can therefore speak of a universally weak violation of the Edwards flatness hypothesis. In most cases, we have

$$\rho_* < \rho_{\text{mid}} < \rho_{\infty}, \quad (99)$$

where $\rho_{\text{mid}} = (\rho_{\text{min}} + \rho_{\text{max}})/2$ is the midpoint of the range of permitted densities. The above rule of thumb expresses that the statistical ensemble tends to favor lower-density blocked configurations, whereas the dynamics tends to favor higher-density blocked configurations. This is illustrated by Table 6, giving the values of $\rho_{\text{min}}$, $\rho_{\text{max}}$, $\rho_{\text{mid}}$, $\rho_*$, and $\rho_{\infty}$ for the Riviera model and four characteristic one-dimensional kinetic spin models whose zero-temperature dynamics can be mapped onto an RSA model. The detailed contents of Table 6 are as follows: Model 1 is the Riviera model, investigated extensively in Sect. 3. The exact value of $\rho_*$ and the numerical value of $\rho_{\infty}$ are respectively given in (78) and in Table 4. For the four subsequent models, both $\rho_*$ and $\rho_{\infty}$ are known exactly. Model 2 is the problem of dimer deposition. The value of $\rho_*$ is not related to (23), because here the system is assumed to be initially empty [56]. The value of $\rho_{\infty}$ is the celebrated result of Flory (see (41)). The last three models concern the Ising chain with an infinite-temperature initial state. Model 3 is the ferromagnetic Ising chain with kinetically constrained zero-temperature Glauber dynamics, investigated extensively in Sect. 2 (see (23) and (43), with $E = 1 - 2\rho$). Model 4 is the ferromagnetic Ising chain with kinetically constrained zero-temperature Kawasaki dynamics [26–30], whereas model 5 is the paramagnetic Ising chain in a uniform magnetic field subjected to zero-temperature either symmetrically or asymmetrically constrained dynamics [23–25]. In the last two cases, the final density $\rho_{\infty}$ (slanted numbers) is smaller than $\rho_{\text{mid}}$ and therefore does not obey the inequality (99).

The most salient qualitative difference between the Riviera model and the kinetically constrained models in the RSA class concerns their final correlation functions. This unlikeliness was somewhat to be expected, since the Riviera model does not enjoy the shielding property. The numerical data shown in Fig. 10 strongly suggest that the connected correlation function $C_{n,\infty} - \rho_{\text{a}}^2$ falls off exponentially, with a decay rate $\mu \approx 0.81$ (see (88)). This observed exponential decay is in stark contrast with the superexponential, inverse factorial decay of connected correlations that is universally met in one-dimensional RSA models. Exponentially decaying correlations are rather viewed as a characteristic of either thermal or otherwise equilibrated systems. From this viewpoint, the Riviera model thus appears as a chimera with, on the one hand, a fully irreversible dynamics leading to metastability with an exponentially large number of attractors and, on the other hand, exponentially decaying correlations germane to those observed at thermal equilibrium.

Acknowledgements It is a pleasure to dedicate this paper to our colleague and friend Malte Henkel on the occasion of his 60th birthday. P.L.K. is grateful to IPhT Paris-Saclay for useful exchanges with Mate Puljiz, Stjepan Šebek, and Josip Zubrinić.
