Abstract

Lombardoite, ideally Ba$_2$Mn$^{3+}$(AsO$_4$)$_2$(OH), and aldomarinoite, ideally Sr$_2$Mn$^{3+}$(AsO$_4$)$_2$(OH), are two new minerals of the arsenbrackebuschite group, discovered in Fe–Mn ore in metaquartzites of the abandoned mine of Valletta, Cunaso, Val Maira, Cuneo Province, Piedmont, Italy. They occur as red–brown and orange brown, respectively, as subhedral crystals (< 0.5 mm) in thin masses, associated with quartz, aegirine, baryte, calcite, hematite, muscovite and Mn minerals such as cryptomelane, braunite and manganberzeliite. Both minerals are translucent, have yellow–orange streak and vitreous lustre. Both are brittle. Estimated Mohs hardness is 6–6½ for lombardoite (by analogy to canosioite), and 4½–5 for aldomarinoite (by analogy to tokyoite). Calculated densities are 5.124 g/cm$^3$ for lombardoite and 4.679 g/cm$^3$ for aldomarinoite. Both minerals are biaxial (+). Lombardoite shows 2V$_z$(meas.) = 78(4)° and is pleochroic with X = yellowish brown, Y = brown and Z = reddish brown (Z > Y > X). Aldomarinoite has 2V$_z$(meas.) = 67.1(1)°, and is pleochroic with X = brown, Y = brownish orange and Z = yellowish brown (Z > Y > X). Point analyses by electron microprobe using wavelength dispersive spectroscopy resulted in the empirical formula (based on 9 O anions): (Ba$_{1.96}$Sr$_{0.17}$Pb$_{0.04}$Na$_{0.02}$Ca$_{0.02}$)$_{1.9+}$ by analogy to tokyoite). Calculated densities are 2V$_z$(meas.) = 78(4)° and is pleochroic with X = yellowish brown, Y = brown and Z = reddish brown (Z > Y > X). Aldomarinoite has 2V$_z$(meas.) = 67.1(1)°, and is pleochroic with X = brown, Y = brownish orange and Z = yellowish brown (Z > Y > X). Point analyses by electron microprobe using wavelength dispersive spectroscopy resulted in the empirical formula (based on 9 O anions): (Ba$_{1.96}$Sr$_{0.17}$Pb$_{0.04}$Na$_{0.02}$Ca$_{0.02}$)$_{1.9+}$

Keywords: lombardoite, aldomarinoite, new mineral, manganese arsenate, crystal structure, Raman spectroscopy, infrared spectroscopy, brackebuschite supergroup, Valletta mine, Cuneo, Piedmont, Italy

Introduction

The discovery of new arsenate mineral species at the Valletta mine dumps, Piedmont, Italy, makes this a significant mineralogical locality. Lombardoite (IMA2016-058, Cámara et al., 2016) and aldomarinoite (IMA2021-054, Cámara et al., 2021) belong to the brackebuschite supergroup of minerals and are the fourth
and the eighth, respectively, of a series of new As-bearing minerals from Valletta Mine (grandaite, SrFe₃(AsO₄)₂(OH)₂, Cámara et al. 2014; braccoite, NaMn₂₋ₓ[Si₃As₂O₇₋ₓ(OH)₃]OH, Cárama et al. 2015; lombardoite, Ba₂Mn³⁺(AsO₄)₂(OH), Cárama et al. 2016; canosioite, Ba₂Fe₆₋ₓ(AsO₄)₂(OH), Cárama et al. 2017; aldomarinoite, SrMn³⁺(AsO₄)₂(OH), Cárama et al. 2021; castellarite, Mn₁₋ₓ(AsO₄)·4.5H₂O, Kampf et al., 2016; and rüdlingerite, Mnₓ⁺V⁵⁺₆As³⁺O₇·2H₂O, Roth et al. 2020). Aldomarinoite represents the fifth Sr-dominate assemblage of the mineral species approved by the Commission on New Minerals, Nomenclature and Classification of the International Mineralogical Association (IMA-CNINMC), after arenogoyazite, SrAl₃(AsO₄)₂(AsO₄)·(OH)₃ (Walent and Dunn, 1984), grandaite, Sr₂Al(AsO₄)₄(OH) (Cámara et al., 2014), kemmlitzite, SrAl₃(AsO₄)(SO₄)(OH)₆ (Hak et al., 1969), oberwolfachite, SrFe₂⁺₆(AsO₄)(SO₄)(OH)₆ (Chukanov et al., 2021), strontioalphamarilite, Sr₀.₆Fe₂⁺₆(AsO₄)₃( OH)₄·4H₂O (Mills et al., 2014), and the second one, after lombardoite, having dominant Mn⁶⁺ instead of Al or Fe³⁺ in the arseno-bridgebite group.

Samples containing lombardoite were collected by Corrado Balestra and Roberto Bracco, whereas aldomarinoite samples were collected by Gian Carlo Piccoli, on the dumps of a dismissed old mine found close to the Valletta pass at the Valletta Valley (‘Vallone della Valletta’ in Italian) in the Maira Valley, Piedmont, Italy, a small Fe–Mn deposit that has never been studied in detail from a geological or petrological point of view. The name of lombardoite honours Dr. Bruno Lombardo (1944–2014), geologist and petrologist at C.N.R. (National Research Council of Italy), for his extensive and sound contributions on the evolution of orogenic belts worldwide. A fragment of the holotype material is deposited in the mineralogical collections of the Museo Regionale di Scienze Naturali di Torino, Sezione di Mineralogia, Petrografia e Geologia, via Giovanni Giolitti 36, I-10123 Torino, Italy, catalogue number M/1 7111. The name aldomarinoite honours Mr. Aldo Marino, the collector and the founding member of the AMI – Italian Micromineralogical Association, born in Dronero (Cuneo Province) in 1942 who, with Gian Carlo Piccoli, first found the Valletta locality. The holotype material is deposited in the mineral collections of the Museo delle Collezioni di Mineralogia, Gemmologia, Petrologia e Giacimentologia, Dipartimento di Scienze della Terra “Ardito Desio”, Università di Milano, Italy, under the catalogue number MCMGPG-H2021–001.

**Geological settings and mineral occurrence**

The discovery area of the two minerals is the Valletta mine, ‘Vallone della Valletta’, Canosio, Val Maira, Cuneo province, Piedmont, Italy (44°23′43″N, 7°53′30″E, 2560 m a.s.l.). The area is geologically located in the Briançonnais Zone of the southern Cottian Alps, not far from the French border line. Geological data of the area are limited and a detailed study of the old mine is missing. The information given here is taken mainly from Crema et al. (1971) and Collo (1997). The quartz cropping out at the Valletta mine belongs to the internal units of the Briançonnais Zone (also known as Axial Permian–Carboniferous Zone), and consists of sedimentary detrital deposits and intermediate–acid volcanic activity rocks (Carboniferous–Permian). A quartzitic formation is located above these, comprising quartz conglomerates (Verrucano formation) and arenaceous quartzites. Then the evaporitic sequence (Lower Triassic) and the carbonate platform rocks such as schistose limestones, limestones and dolomites follow. Sedimentation of dolomitic breccias occurs during Upper Triassic followed again by evaporites. Then another transgressive phase occurs, characterised by carbonaceous sedimentation (Cretaceous–Lower Eocene). Finally, the Eocene–Oligocene period consists of calcarenites from detrital and turbidite facies.

In the Valletta mine, the volume of the mineralised body is limited to the surface and the mine dumps are the main remains of the former mining activities (Fig. 1). They consist of yellowish limestones–dolostones and red–brown quartzites and silicoclastic rocks, which contain calcareous, quartzitic and volcanic clasts with variable dimensions from a few millimetres to ~15 centimetres. The quartzitic rocks are composed of quartz conglomerates of the Alpine Verrucano and arenaceous quartzites (Upper Permian–Lower Triassic); the quartzites cover the conglomerates and the fine-grained quartz–feldspar schists derived from the acid volcanism. Above the quartzites, the limestones–dolostones consist of schistose limestones, yellow dolostones and an alternation of limestones and dolostones. From a tectonic point of view, the Valletta area is part of the Marinet anticlinorium, or the siliceous Bande de Marinet, the southern tectonic zone of the internal units, and the Sauron unit.

In the mine dumps, the quartzites and the calcareous rocks are often fractured, and show quartz and calcite veins containing mineral phases rich in As, V, Mn, Ba and Sr, which are also present along the fault planes (Fig. 2). These minerals are probably the result of crystallisation from hydrothermal fluids and oxidising conditions, as suggested by the presence of hematite, braunite and cryptomelane.

The present new minerals are associated strictly with quartz, aegirine, baryte, calcite, hematite, muscovite and Mn minerals such as cryptomelane, braunite and manganberzelite. Other minerals that have been observed in the same locality are: adelite, albite, arsensioleite, azurite, bariopharmacosiderite, berzelite, boisite, braccoite, canosioite, canyinite, castellarite, coralloite, diopside, fíanelite, fluorapatite, gamagarite, ganophyllite, grandaite, gypsum, hollandite, ilmenite, magnesio-arvedsonite, magnesio-riebeckite, magnetite, malachite, mimetite, neotocite, opal, orthoclase, oxy-dravite, palenzonite, phlogopite, picolinite, pyrobohelite, ranciéite, rhodochrosite, rhodonite, richterite, rüdlingerite, rutile, sanerote, talc, tetrahedrite series minerals, thorianite, tilasite, tinnunculite, tiragalloite, titaneite, tokyoite and wallkildellite.

**Appearance and physical properties**

Lombardoite (Fig. 3) and aldomarinoite (Fig. 4) occur as subhedral crystals in thin masses, a few cm in size, with uneven fracture, or aggregates of small crystals (<0.05 mm), in white veins of compact quartz or along the fault planes, as a reddish-brown quartzitic mass. Well-formed crystals, typically platy tablets, are very rare. Single crystals of lombardoite are dark red–brown, whereas aldomarinoite crystals are dark orange. Both are translucent, have a yellow–orange streak and a vitreous lustre. Lombardoite and aldomarinoite are optically biaxial (+). Lombardoite has 2Vᵣ(meas.) = 78(4)° and is pleochroic with X = yellowish brown, Y = brown and Z = reddish brown (Z > Y > X); the mean refractive index (nₑₑ) obtained from the Gladstone–Dale relationship (Mandarino, 1979, 1981) using the empirical formulae and calculated densities is 1.86, which is far beyond our available experimental range. Aldomarinoite has 2Vᵣ(meas.) = 67.1(1)°, measured using a spindle stage mounted in a Leitz Dialux...
Microscope with polarised light, and with optical calculations made with the Excelibr spreadsheet (Steven and Gunter, 2018). Aldomaroite is pleochroic with $X = \text{brown}$, $Y = \text{brownish orange}$ and $Z = \text{yellowish brown}$ ($Z < Y < X$) and the calculated mean refractive index is 1.83 (from the Gladstone–Dale relationship). Both minerals are brittle, and no cleavage or parting is observed. Hardness was not measured but assigned by analogy to canosioite (6–6½) for lombardoite, and to tokyoite (4½–5) for aldomaroite. Density was not measured due to the small crystal size and the frequent micro inclusions of other phases. The calculated density obtained from the empirical formula and unit-cell parameters measured during the single-crystal study is 5.124 g/cm$^3$ for lombardoite and 4.679 g/cm$^3$ for aldomaroite.

Micro-Raman spectroscopy

The Raman spectrum of lombardoite (Fig. 5, upper spectrum) was obtained using a micro/macro Jobin Yvon Mod. LabRam HRVIS at the University of Torino, whereas the aldomaroite spectrum (Fig. 5, lower spectrum) was obtained using a high resolution confocal micro-Raman system (LabRam HR Evolution – Horiba at the University of Milano), both equipped with a motorised x–y stage. The back-scattered Raman signal was collected with a 50× objective and the Raman spectrum was obtained for a non-oriented crystal. The 532 nm line was used as excitation; laser power was controlled by means of a series of density filters. The system was calibrated using the 520.6 cm$^{-1}$ Raman band of silicon. The spectra were collected with multiple acquisitions (5 to 10 for lombardoite, 3 for aldomaroite) with single counting times ranging between 10 and 20 s for lombardoite and between 30 and 40 s for aldomaroite. The spectrum was recorded using the Horiba LabSpec 5 (lombardoite) and LabSpec 6 (aldomaroite) software packages from 100 to 4000 cm$^{-1}$ for lombardoite and from 50 to 4000 cm$^{-1}$ for aldomaroite, the results of the spectroscopic analysis are reported below.

The presence of $(\text{AsO}_4)^{3-}$ is confirmed. Although in many cases it is very difficult to separate the contributions of arsenate from those of vanadate units, a comparative analysis of Raman spectra of other members of the brackebuschite supergroup allows...
the identification of two main bands in the region of 750–950 cm$^{-1}$, centred at ca. 818 and 871 cm$^{-1}$ (plus two weak shoulders at 759 and 914 cm$^{-1}$) for lombardoite and at ca. 848 and 892 cm$^{-1}$ (plus three weak shoulders at 776, 816 and 932 cm$^{-1}$) for aldomarinoite, they are slightly shifted compared to those found for canosioite (838, 862 and 896 cm$^{-1}$, Câmara et al., 2017) and grandaite (at 833, 857 and 899 cm$^{-1}$, Câmara et al., 2014), although the band at $\sim$850 cm$^{-1}$ is not clearly resolved in the Raman spectrum of lombardoite. These two main bands that are convoluted in lombardoite can be assigned to the stretching modes of (AsO$_4$)$_3$– and (VO$_4$)$_3$– groups respectively (the 871 cm$^{-1}$ one is weaker due to the lower content of VO$_4$ in lombardoite). A broad and weak band is observed at 627 cm$^{-1}$. Similar band frequencies have been observed for canosioite (Câmara et al., 2017) where multiple bands are shifted to higher frequencies.

In the region 200–600 cm$^{-1}$ multiple Raman bands are observed at 293, 328 and 356 cm$^{-1}$ for lombardoite and at 202, 297, 338 and 374 cm$^{-1}$ for aldomarinoite (As$_5^{5+}$–O bending vibrations); further bands are observed at 405, 471 and 505 cm$^{-1}$ for lombardoite and at 411, 453, 488, 508, 529 and 612 cm$^{-1}$ for aldomarinoite. Bands lower than 200 cm$^{-1}$ correspond to M–O and lattice modes (88, 103, 163 and 181 cm$^{-1}$ for lombardoite and 67, 91, 114, 126 and 160 cm$^{-1}$ for aldomarinoite).

No bands were observed in the range between 2500 and 4000 cm$^{-1}$ in the Raman spectrum of lombardoite. The absence of strong bands with frequencies higher than 1000 cm$^{-1}$ would indicate the absence of OH groups in lombardoite. Same difficulties on observing bands in the range between 2500 and 4000 cm$^{-1}$ of the Raman spectrum was found in grandaite (Câmara et al., 2014) and canosioite (Câmara et al., 2017). However, a broad band centred at ca. 2970 cm$^{-1}$ was observed in this range in the Raman spectrum of aldomarinoite, which agrees well with the value calculated with the equation $3592 - 304 \times 10^9 \exp(-d(O\cdots O)/0.1321)$ (Libowitzky, 1999), i.e. 3108 cm$^{-1}$.

**Infrared spectroscopy**

Fourier-transformed infrared (FTIR, Fig. 6) transmission spectra (64 scans) of lombardoite were recorded using a diamond anvil cell (High Pressure Diamond Optics, Inc.). They were obtained...
with a spectrophotometer Bruker Vertex 70 coupled with a Hyperion 3000 microscope at Centro Conservazione e Restauro “La Venaria Reale” (CCR, Torino, Italy). The instrument is equipped with an MCT detector (Infrared Associates Inc.), working in the spectral range from 4000 to 600 cm\(^{-1}\) with an average spectral resolution of 4 cm\(^{-1}\). The FTIR spectrum obtained for lombardoite shows the presence of a broad weak band at \(\sim 2900\) cm\(^{-1}\) that could be assigned to the stretching of OH groups. This band agrees well with Raman spectroscopy observations. Thus, in the absence of F in the electron microprobe analysis and on the basis of crystal structure refinement (SREF) data (see below) we also consider the occurrence of (OH) groups in lombardoite. As the FTIR spectrum has no absorption band at ca. 1650 cm\(^{-1}\) (e.g. bending vibration) the presence of H\(_2\)O groups can be ruled out.

**Optical absorption spectroscopy (OAS)**

Polarised optical absorption spectra of double sided polished single-crystal absorbers of lombardoite prepared from X–Y (32 μm thick) and Y–Z (24 μm thick) sections were recorded in the range 9000–34000 cm\(^{-1}\) using an AVASPEC-ULS2048X16 spectrometer attached via a 400 μm UV optic fibre cable to a Zeiss Axiotron UV-microscope. A 75 W Xenon arc lamp was used as a light source and Zeiss Ultrafluar 10× lenses served as objective and condenser. The size of the circular measure aperture was 32 μm in diameter. A UV-quality Glan-Thompson prism with a working range from 250 to 2700 nm (40,000 to 3704 cm\(^{-1}\)) was used as the polariser. The recorded spectra (Fig. 7) show three intense and broad absorption bands at 22,900, 22,100 and 18,300 cm\(^{-1}\). An additional broad band of medium intensity occurs at 12,000 cm\(^{-1}\). Observed bands and their intensities, band-widths and energies are typical for spin-allowed electronic d-d transitions observed in spectra of minerals containing strongly elongated or compressed octahedra occupied by Mn\(^{3+}\), for example as observed in piemontite and kanonaite (e.g. Smith et al., 1982). From the observed band energies, the crystal field splitting parameter (10 \(D_q\)) for Mn\(^{3+}\) at the M-site of lombardoite is calculated to be 15,100 cm\(^{-1}\). This compares very well with 10 \(D_q\) values in the range 14,400 to 15,600 cm\(^{-1}\) for Mn\(^{3+}\) in epidote and andalusite-group minerals, suggesting a mean Mn–O bond distance in lombardoite of \(\sim 2.02\) Å.

**Chemical data**

The chemical composition of lombardoite was determined using a Cameca SX-50 electron microprobe in wavelength dispersive spectroscopy (WDS) mode at the Institute of Environmental Geology and Geoengineering (IGAG – C.N.R., Rome) on the same crystal used for structure determination. Major and minor elements were determined at 15 kV accelerating voltage and 15 nA beam current (beam size = 1 μm), with 40 to 20 s counting time on both peak and background. Fluorine, Si, K, Ti, Cr, Ni,
Cu and Zn were below the detection limit. Analytical results, standards and spectral line are reported in Table 1. The chemical composition of aldomarinoite was determined by WDS using a Jeol 8200 Super Probe electron microprobe at the University of Milano operating at an acceleration voltage of 15 kV and beam current of 5 nA (beam size = 3 μm). Potassium, Na, Ti, Si and F were below the detection limit of 0.03 atoms per formula unit (apfu). Analytical results, standards and spectral line are reported in Table 1.

Both the analyses were subject to ZAF-corrections using the PAP routine (Pouchou and Pichoir, 1985). For both minerals, H2O was calculated based on one OH group per formula unit (apfu) (see Raman and FTIR spectroscopy sections). Manganese was also considered as Mn\textsuperscript{3+} on the basis of high oxidising environments as well as OAS results. All Fe was considered to be Fe\textsuperscript{3+} based on the Mn redox potential arguments; S.D. – standard deviation.

### Table 1. Analytical data (wt.%) for lombardoite (5 data points) and aldomarinoite (4 data points).

|                | Lombardoite Mean | Range | S.D. | Probe standard | Lombardoite Mean | Range | S.D. | Probe standard |

#### Single-crystal X-ray diffraction

Data for lombardoite were collected using an Oxford Gemini R Ultra diffractometer equipped with a CCD area detector at CrisDi (Università di Torino, Italy), with graphite-monochromatised MoKα radiation. Crystal data and experimental details are reported in Table 3. At room temperature, the unit-cell parameters were: a = 7.5414(3) Å, b = 5.9838(2) Å, c = 8.7399(3) Å, β = 112.034(4)° and V = 365.60(2) Å\textsuperscript{3}.

Data for aldomarinoite were collected using a Rigaku XtaLAB Synergy-S at the University of Milano, equipped with a microfocus MoKα source and a HyPix-6000HE detector with graphite-monochromatised MoKα radiation. Crystal data and experimental details are reported in Table 3. At room temperature, the unit-cell parameters were: a = 7.5577(4) Å, b = 5.9978(5) Å, c = 8.7387(4) Å, β = 111.938(6)°, V = 367.43(3) Å\textsuperscript{3}, space group = P2\textsubscript{1}/m and Z = 2. A total of 1755 independent reflections were collected.

The two structure models were refined starting from the atom coordinates of arsenbrackebuschite (Hofmeister and Tillmanns, 1978) for lombardoite and of grandaite (Cámara et al., 2014) for aldomarinoite, by means of the SHELX set of programs (Sheldrick, 2015).

Scattering curves for neutral atoms were taken from the International Tables for Crystallography (Wilson, 1992). Site-scattering values were refined for the cation sites using two scattering curves contributing proportionally and by constraining the sum to full occupancy: As and V were used for the 1(1) and 2(2) sites; Al and Mn were considered for the M site; Ba and Sr were used for the A(1) and A(2) sites in lombardoite, whereas for aldomarinoite Sr and Ca were used for the A(1) site; and Sr and Ba for the A(2) site. A peak in the difference-Fourier map was found close to O(7) and added to the model as an H atom with fixed coordinates for aldomarinoite and refined coordinates for lombardoite. An isotropic displacement factor of 1.2 times the one observed for the bonded O(7) anion site, and full occupancy

### X-ray crystallography

#### Powder X-ray diffraction

The powder X-ray diffraction pattern of lombardoite was obtained with an Oxford Gemini R Ultra diffractometer equipped with a CCD area detector at CrisDi (University of Turin). Experimental and calculated data are reported in Table 2. The unit-cell parameters refined from the powder data with the software UnitCell (Holland and Redfern, 1997) are: a = 7.8636(1) Å, b = 6.13418(1) Å, c = 9.1197(1) Å, β = 112.660(2)°, V = 405.94(1) Å\textsuperscript{3}, space group = P2\textsubscript{1}/m and Z = 2.

Data for aldomarinoite were collected using a Rigaku XtaLAB Synergy-S at the University of Milano, equipped with a microfocus MoKα source and a HyPix-6000HE detector with graphite-monochromatised MoKα radiation. Crystal data and experimental details are reported in Table 3. At room temperature, the unit-cell parameters were: a = 7.5577(4) Å, b = 5.9978(5) Å, c = 8.7387(4) Å, β = 111.938(6)°, V = 367.43(3) Å\textsuperscript{3}, space group = P2\textsubscript{1}/m and Z = 2. A total of 1755 independent reflections were collected.

Scattering curves for neutral atoms were taken from the International Tables for Crystallography (Wilson, 1992). Site-scattering values were refined for the cation sites using two scattering curves contributing proportionally and by constraining the sum to full occupancy: As and V were used for the 1(1) and 2(2) sites; Al and Mn were considered for the M site; Ba and Sr were used for the A(1) and A(2) sites in lombardoite, whereas for aldomarinoite Sr and Ca were used for the A(1) site; and Sr and Ba for the A(2) site. A peak in the difference-Fourier map was found close to O(7) and added to the model as an H atom with fixed coordinates for aldomarinoite and refined coordinates for lombardoite. An isotropic displacement factor of 1.2 times the one observed for the bonded O(7) anion site, and full occupancy

were applied. Refinement converged to R₁ = 0.0197 for 2628 observed reflections with F₁ > 4σ(F₁) and 87 parameters for lombardoite and to R₁ = 0.0345 for 1235 observed reflections with F₁ > 4σ(F₁) and 83 parameters for aldomarinoite. Tables 4, 5 and 6 report, respectively, atom coordinates, displacement parameters, and selected bond distances and angles. Bond valence calculations using the parameters of Gagné and Hawthorne (2015) are reported in Table 4. The crystallographic information file has been deposited with the Principal Editor of Mineralogical Magazine and is available as Supplementary material (see below).

Description of the structure

Cation sites

M sites

There is one M site hosting small high-charge cations in octahedral coordination. The observed site scattering value 22.576(3) eps (electrons per site) at the M site of lombardoite and 20.49(7) eps at the M site of aldomarinoite agree with the chemical data confirming a Mn dominance at that site. Those correspond to (Me_{0.67} + Fe^{3+}_{0.14} + Mg_{0.12} + Al_{0.07})_2.00 apfu and 22.50 eps, and (Me_{0.46} + Al_{0.33} + Fe^{3+}_{0.20} + Mg^{2+}_{0.01})_2.00 apfu and 21.11 eps, respectively.

The observed average bond length at M sites (2.030 Å for lombardoite and 1.981 Å for aldomarinoite, Table 6) is too small for the Fe^{3+} and Mn^{2+} ions; the incident bond valence sum at the M site is in agreement with average formal charge being dominantly +3, i.e. considering both Fe^{3+} and Mn^{2+} at the M sites, which also agrees with the oxidised nature of the ore.

A sites

There are two non-equivalent sites hosting large divalent cations in eight and eleven coordination: the A site occupancies of aldomarinoite show little difference in scattering values: 35.05(9) eps at the A(1) site and 38.70(7) eps at the A(2) site. Therefore, we assign (Ba_{0.94}Sr_{0.06})_{0.1} to A(1) and (Ba_{1.00})_{0.9} to A(2). The refined SREF results that show little difference in scattering values at both sites of lombardoite: 53.44(1) eps at the A(1) site, and 38.70(7) eps at the A(2) site. Therefore, we assign (Ba_{1.00})_{0.9}Sr_{0.1} to A(1) and (Ba_{1.00})_{0.9} to A(2). Also the A site occupancies of aldomarinoite show little difference in the scattering values: 35.05(9) eps at the A(1) site and 38.70(7) eps at the A(2) site. Therefore, we assign (Sr_{0.81}Ca_{0.19})_{0.1} to A(1) and (Sr_{0.81}Ca_{0.19})_{0.1} to A(2). Bond valence calculations indicate that both the A(1) and A(2) sites are compatible with the dominance of divalent cations at these sites.

T sites

There are two non-equivalent sites hosting a high charge cation in tetrahedral coordination: the T(1) and the T(2) sites. The refined

Anion sites

There are seven anion positions in the structure of lombardoite and aldormarinoite, two of them on general position, accounting for a total of 18 anions per unit cell. Bond valence data (Table 4) show that one out of seven anion sites has bond valence sum close to 2 v (valence units), whereas the O(7) site has a smaller contribution (1.341 v for lombardoite and 1.400 v for aldormarinoite) compatible with the occurrence of monovalent anion at this site. The absence of F in the chemical analyses (Table 1) indicates that the O(7) site must therefore host a hydroxyl group. In fact, a maxima was found in the Fourier difference and added to the model as atom H(7). The hydrogen at H(7) is at 1.64 Å from the O(5) atom, which has a bond-valence sum of 1.503 v for lombardoite and is at 1.791 Å from the O(5)

Structure topology

The crystal structures of lombardoite and aldomarinoite (Fig. 8) are topologically identical to that of arsenbrackebuschite. Chains of \[M^{3+}\text{O}_4\text{O}^2\text{(OH,H}_2\text{O)}\] units are connected through interstitial divalent cations. The \[M^{3+}\text{O}_6\] octahedron shares edges with other octahedra forming a chain along [010]. The shared

edge has one anion that can be an (OH) group or a $H_2O$ group, depending on the charge of the $M$-cation at the octahedron, and the other anion is shared with the apex of a $T^5O_4$ tetrahedron (the T1(1) site). The remaining 4 anions coordinating the octahedron are linked to the edge of another $T^5O_4$ tetrahedron (the T2(2) site) alternating in both sides. Minor $V^{5+}$ is disordered among the two arsenate tetrahedra. Decorated chains of octahedra link together through bonding with two symmetrically independent interstitial cations at the A(1) and A(2) sites, and hydrogen bonding. In arsenbrackebuschite, Pb occupies both the A sites but is shifted off-centre, as usual, for its lone pair configuration. The small quantity of Pb found in lombardoite and aldomarinoite at the A(2) site also follows this configuration. The Pb off-centre displacement has been reported previously in the literature [e.g. synthetic $\text{Pb}_2(\text{Pb},\text{K})_2(\text{SiO}_2)_2\text{O}$, Moore et al., 1985; Pb replacing Ba in hyalotekite, Moore et al., 1982 and Christy et al., 1998, or Pb replacing REE in lusernite-(Y), Biaigioni et al., 2013]. The distortion observed for the T(2)O4 tetrahedron along with the low bond valence incidence at O(5) represents a stressed environment for the structure of lombardoite and aldomarinoite.

Related minerals
Lombardoite, $\text{Ba}_2\text{Mn}^{3+}(\text{AsO}_4)_{2}(\text{OH})$, is the As-dominant analogue of tokyoite, $\text{Ba}_2\text{Mn}^{3+}[(\text{VO}_4)]_{2}(\text{OH})$ and the Ba–As-dominant analogue of brackebuschite, $\text{Pb}_2\text{Mn}^{3+}[(\text{VO}_4)]_{2}(\text{OH})$. It is the first Mn–As member of the arsenbrackebuschite group in the brackebuschite supergroup (Table 7).

Aldomarinoite, $\text{Sr}_2\text{Mn}^{3+}(\text{AsO}_4)_{2}(\text{OH})$, is the Sr-dominant analogue of lombardoite, $\text{Ba}_2\text{Mn}^{3+}[(\text{AsO}_4)]_{2}(\text{OH})$, and the Mn$^{3+}$-dominant analogue of grandaite, $\text{Sr}_2\text{Al}(\text{AsO}_4)_{2}(\text{OH})$. It is the second Sr member of the arsenbrackebuschite group of the brackebuschite supergroup (Table 7).

In the Strunz System (Strunz and Nickel, 2001) lombardoite and aldomarinoite fit in subdivision 8.B.G, phosphates, etc. with additional anions, without $H_2O$, with medium-sized and large cations (OH, etc.).

Costin et al. (2015) reported an As-rich tokyoite with the formula ($\text{Ba}_{1.92}\text{Sr}_{0.05}\text{Pb}_{0.03}$)$_{2}(\text{Fe}_{0.98}\text{Mn}_{0.02})_2(\text{As}_{1.050}\text{V}_{0.950})_2\text{O}_8\text{O}_4(\text{OH})$ from a drill core obtained from the Postmasburg area in the Northern Cape Province of South Africa. Their observations indicated a possible replacement of tokyoite by a composition richer...
in As, with an almost complete solid solution from a pure tokyoite towards an As-dominant end-member, reaching compositions of almost 50:50. The grains were associated with K-feldspar, serandite, quartz, witherite, tokyoite and noelbensomite. These authors reported cell parameters obtained by electron backscatter diffraction (a = 9.121 Å, b = 6.142 Å, c = 7.838 Å, α = γ = 90°, β = 112°, monoclinic and P21/m space group), which compare well with the ones we obtained for lombardoite (Table 3). Costin et al. (2015) also reported Raman spectra of As-rich tokyoite. The assignment of Raman peaks in As-rich tokyoite was done by similarity with arsenosumebite by Cosin et al. (2015), and suggested a possible ordering of the AsO4 and VO4 tetrahedra. In detail, they observed peaks at 308–340 cm−1, assigned to (AsO4)3− bending modes and at 442–460 cm−1 assigned to (AsO4)3− and (VO4)3− bending modes. Moreover, Costin et al. (2015) also reported four outstanding peaks between 830 cm−1 and 935 cm−1, a pair between 830–846 cm−1 with a weak band at 730 cm−1 [symmetrical stretching vibrations and asymmetrical stretching vibrations of (AsO4)3−, respectively], and a pair between 906 and 935 cm−1 [symmetrical stretching vibrations and asymmetrical stretching vibrations of (VO4)3−, respectively]. However, the latter two peaks were at higher wave numbers than expected for the VO4 group in brackebuschte, and this was interpreted as due to the Jain–Teller distortion effects related to Mn3+. Though our samples are almost devoid of V, we observe similar peaks, corresponding to symmetric bending modes for AsO4 at 328 cm−1 and the most intense band corresponding to symmetric stretching modes for AsO4 at 818 cm−1 (with two unresolved shoulders at 871 and 759 cm−1) in lombardoite. The wave numbers for the corresponding band in aldmarinoite are shifted to higher wave numbers (339, 773, 849 and 893 cm−1) probably because of the different bond strength with Sr at the A sites.
