ABSTRACT
With the spatial resolution of the Atacama Large Millimetre Array (ALMA), dusty galaxies in the distant Universe typically appear as single, compact blobs of dust emission, with a median half-light radius, $\approx 1$ kpc. Occasionally, strong gravitational lensing by foreground galaxies or galaxy clusters has probed spatial scales 1–2 orders of magnitude smaller, often revealing late-stage mergers, sometimes with tantalising hints of sub-structure. One lensed galaxy in particular, the Cosmic Eyelash at $z = 2.3$, has been cited extensively as an example of where the interstellar medium exhibits obvious, pronounced clumps, on a spatial scale of $\approx 100$ pc. Seven orders of magnitude more luminous than giant molecular clouds in the local Universe, these features are presented as circumstantial evidence that the blue clumps observed in many $z \sim 2$–3 galaxies are important sites of ongoing star formation, with significant masses of gas and stars. Here, we present data from ALMA which reveal that the dust continuum of the Cosmic Eyelash is in fact smooth and can be reproduced using two Sérsic profiles with effective radii, 1.2 and 4.4 kpc, with no evidence of significant star-forming clumps down to a spatial scale of $\approx 80$ pc and a star-formation rate of $< 3 M_\odot$ yr$^{-1}$.

Key words: galaxies: high-redshift — galaxies: starburst — submillimetre: galaxies — infrared: galaxies — galaxies: structure

1 INTRODUCTION

Interferometric submillimetre (submm) observations of distant, dusty, star-forming galaxies (DSFGs, sometimes known as submm-selected galaxies – SMGs) — intense starbursts with star-formation rates (SFRs) in excess of $100 M_\odot$ yr$^{-1}$ — have revealed a consistent morphological picture. Ignoring multiplicity and signatures associated with galaxy interactions and mergers, of which there are many examples, the thermal continuum emission from each is usually dominated by a single, compact blob of dust — expected to be largely co-spatial with the molecular gas — with a median half-light radius, 0.2–0.3 arcsec or $\approx 1$ kpc (Ikarashi et al. 2015, 2017; Simpson et al. 2015; Hodge et al. 2016; Oteo et al. 2016, 2017a; Rujopakarn et al. 2016; Gullberg et al. 2018; Rujopakarn et al. 2019; Ma et al. 2019).

In a handful of cases it has been possible to probe spatial scales nearly an order of magnitude smaller, $\approx 150$ pc or $\approx 20$ milliarcsec (mas), using the longest available baselines, aided in one case by a bright, compact, in-beam calibrator (Oteo et al. 2017b). The findings are consistent — compact blobs of dust emission, occasionally multiple blobs suggestive of mid-stage mergers (Iono et al. 2016; Tadaki et al. 2018). There have been glimpses of sub-structure, of which the re are associated with galaxy interactions and mergers, of which the re are consistent — compact blobs of dust emission, occasionally

2019 December 19
dust clumps, several of which can be seen at multiple frequencies, on approximately the scale of the synthesised beam ($\approx 150$ mas, or $\approx 200$ pc), which supports more ambiguous evidence\(^1\) from maps of CO(5–4) and CO(8–7) that the gas distribution is clumpy.

Even more robust, though difficult to visualise because of the extreme gravitational amplification that gives rise to its name, are the dozen or more molecular clouds uncovered by recent 0.2-arcsec FWHM imaging in CO(4–3) of the Cosmic Snake, at $z = 1.036$, by Dessauges-Zavadsky et al. (2019). Each of these clouds is at least an order of magnitude more massive and turbulent than those in the Milky Way today, and there is a substantial spatial disconnect between the gas and the twenty clumps seen in Hubble Space Telescope imaging (Cava et al. 2018) which Dessauges-Zavadsky et al. had expected to detect in CO.

Cited extensively as the definitive example of where the interstellar medium (ISM) exhibits dusty star-forming clumps is the case of SMM J121352–0102, or the Cosmic Eyelash, named due to its shape and its proximity to the Cosmic Eye (Smail et al. 2007; Swinbank et al. 2010). The Cosmic Eyelash lies behind the $z = 0.325$ galaxy cluster, MACS J2135–01, which amplifies it gravitationally by a factor, $\mu = 37.5$. With its spectral energy distribution (SED) peaking at $\lambda_{\text{obs}} \approx 350$ µm at a flux density, $\approx 500$ mJy (Ivison et al. 2010) — so typical intrinsically of an SMG close to the confusion limit for a 10–15-m single dish — and with an SED that has proved invaluable for FIR/submm photometric redshift estimation (e.g. González-Nuevo et al. 2019), it was the first SMG sufficiently bright to allow a blind redshift to be obtained, $z = 2.3$. This was determined by Swinbank et al. (2010) via detection of CO $J = 1–0$ using the Green Bank Telescope, a few months ahead of the blind detection of CO $J = 3–2$ and $J = 5–4$ from SMM J14009+0252 by Weiß et al. (2009). The Cosmic Eyelash was also sufficiently bright to allow FIR spectroscopy with the Herschel SPIRE FTS (George et al. 2014; Zhang et al. 2018a).

Early interferometric follow-up by Swinbank et al. (2010), using the eight-element Submillimeter Array (SMA) in its most extended (VEX) configuration, provided evidence of at least five and as many as eight bright, compact, dusty clumps. The most tempting lensing configuration suggested four on each side of a caustic, each with an intrinsic spatial scale of $\approx 100$ pc, where the morphology of the molecular gas seen in later imaging by Swinbank et al. (2011) was described as ‘broadly aligned’ with the continuum clumps.

More than any other submm data, the discovery of these dust clumps in the Cosmic Eyelash has been cited (even quite recently – Guo et al. 2018; Meng & Gnedin 2019) as circumstantial evidence that the giant ($\approx 0.1$–1 kpc) off-centre clumps — typically found in broadband rest-frame ultraviolet (UV)–optical images of $z \approx 1$–3 galaxies (e.g. Cowie et al. 1995; Conselice et al. 2004; Elmegreen & Elmegreen 2005; Elmegreen et al. 2008, 2013; Genzel et al. 2011), and especially in IR-luminous galaxies (Calabrò et al. 2019) — are important sites of star formation, albeit perhaps short lived (Genel et al. 2012; Kruisjes et al. 2019; Chevance et al. 2019, cf. Bournaud et al. 2014). Bright in Hα (Livermore et al. 2012, 2015), these blue clumps are thought to harbour significant star formation\(^2\) (though less than 10 per cent

\(^1\) Due to the possibility of excitation effects, or the patchy destruction of CO by cosmic rays (e.g. Bisbas et al. 2017).

\(^2\) One might ask why, since with adequate spatial resolution we generally find a disconnect between active star formation and blue light, and would anyway expect the dusty gas to be expelled rapidly, post-starburst, such that the ratio of UV to submm clumps may reflect the lifetimes for each phase.

Figure 1. Top: VEX-only SMA image of the Cosmic Eyelash from Swinbank et al. (2010), where we have reproduced the contours shown in that paper as faithfully as possible, at 3, 4, 5 ... $\sigma$, where the r.m.s., $\sigma = 2.1$ mJy beam$^{-1}$. Below: our observed ALMA 251-GHz (band-6) continuum image (see §3), which goes $40\times$ deeper than the SMA image after accounting for the shape of the SED, with contours at 3, 6, 12, 24 ... $\sigma$. Each panel has the caustic illustrated, and the respective synthesised beam.
mass function and a standard Λ-CDM cosmology with $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$ and $H_0 = 70\text{ km s}^{-1}\text{ Mpc}^{-1}$, where $1\text{ arcsec}$ at $z = 2.3$ corresponds to $8.2\text{ kpc}$.

2 OBSERVATIONS AND DATA REDUCTION

The Cosmic Eyelash has been observed several times with ALMA, predominantly in bands 6 and 7. From these, we have selected a subset with good sensitivity ($\leq 50\mu\text{Jy beam}^{-1}$) and angular resolution ($\Delta\theta \leq 0.3\text{ arcsec}$). Although mostly designed to observe various molecular transitions, these data contain a significant fraction of line-free channels that allow sensitive continuum maps to be made. One project used ALMA’s maximum-bandwidth ($\Delta\nu = 7.5\text{ GHz}$) ‘single-continuum’ (SC) mode and — although a little less sensitive than the others, due to less observing time — contains both an extended and compact configuration and is thus particularly sensitive to low-brightness extended emission. All observations were conducted in dual-polarisation mode with low-spectral-resolution time-division mode (TDM) spectral windows, i.e. with $2\text{ GHz}$ of usable bandwidth. See Table 1 for a summary of the band-6 and -7 ALMA observations considered for our study.

Data reduction was carried out using the Common Astronomy Software Application package, with calibration performed using the ALMA Science Pipeline. Contamination from molecular lines was identified by combining all baselines to produce a spectrum, with affected channel ranges then flagged. Imaging was performed subsequently, using TCLEAN with a Briggs weighting scheme (ROBUST $\approx -0.5$). Self-calibration was used (first in phase, then in amplitude and phase) to produce the final continuum maps. Each configuration of the 2012.1.01029.S data was mapped and self-calibrated separately. Additional self-calibration of the combined map was necessary to correct for small errors in the relative astrometry and flux-density scales.

The most sensitive map was obtained from the band-6 data (rest-frame 360 $\mu\text{m}$, where we probe emission from cold dust), published previously as part of a survey of luminous, dusty galaxies (Falgarone et al. 2017). The r.m.s. noise level was $\sigma = 21\mu\text{Jy beam}^{-1}$ and the synthesised beam measured $0.23\times0.16\text{ arcsec}^2$ (FWHM), with the major axis at a position angle $\theta = 15^\circ$ (PA, measured East of North) of $93^\circ$.

In band 7, the map with the best sensitivity and highest angular resolution was that produced from the 2012.1.00175.S data, intended originally to trace OH$^+$ and H$_2$O (average frequency, $303.9\text{ GHz}$; rest-frame $300\mu\text{m}$). A continuum map of these data has already been published by Indriolo et al. (2018) but our map has a significantly higher dynamic range and a sensitivity of $\sigma = 33\mu\text{Jy beam}^{-1}$.

Figure 2. ALMA images of the Cosmic Eyelash, as listed in Table 1 and described in §3, displayed using linear greyscales from zero to the peak observed flux density, with contours at $-12$, $-6$, $-3$, $3$, $6$, $12\ldots\sigma$. Each panel has the caustic illustrated, and also the synthesised beam, lower left.

| ALMA project            | Detected species(a) | $\nu_0$ (GHz) | $\sigma$ /$\mu$Jy beam$^{-1}$ (c) | Beam (FWHM) /mas$^{(e)}$ |
|-------------------------|---------------------|---------------|----------------------------------|--------------------------|
| 2012.1.00175.S          | OH$^+$, H$_2$O      | 303.9         | 27                               | $174 \times 148^{(f)}$   |
| 2012.1.00175.S          | H$_2$O              | 356.4         | 48                               | $232 \times 167$         |
| 2012.1.01029.S          | SC                  | 345.0         | 60                               | $282 \times 246$         |
| 2016.1.00282.S          | CH$^+$              | 251.0         | 21                               | $225 \times 160$         |

Notes: (a) SC refers to a ‘single-continuum’ set up; (b) average frequency, after flagging of line-contaminated channels; (c) continuum sensitivity; (d) synthesised beam size, FWHM; (e) for the average magnifications across the Cosmic Eyelash, this corresponds to linear scales along the major and minor axes of $130$ and $820\text{ pc}$ in the source plane, respectively.

27 $\mu$Jy beam$^{-1}$. The synthesised beam was somewhat smaller than that of the band-6 map, $0.17 \times 0.15\text{ arcsec}^2$ at PA $= 66^\circ$. A second dataset from the same project, targeting H$_2$O at a higher frequency, $356.4\text{ GHz}$, produced a similar map, though not quite as sensitive. The synthesised beam of the band-7 pure-continuum map was competitive with the other maps, $0.28 \times 0.25\text{ arcsec}^2$, PA $= 104^\circ$, with a sensitivity of $\sigma = 60\mu\text{Jy beam}^{-1}$.

3 RESULTS

We quickly and simply illustrate the purpose of this paper in Fig. 1, which shows the SMA image$^{3}$ of Swinbank et al. (2010) alongside our deep ALMA band-6 continuum image. The ALMA image is $\approx 40\times$ deeper than the SMA image, even after accounting for the $2.6\times$ drop in observed dust emission between 345 and 251 GHz. In all important respects the ALMA band-6 image has the same morphological characteristics as our band-7 imaging (see Fig. 2), which is more than $50\times$ deeper than the SMA image, with a smaller and more symmetric synthesised beam. On the scales probed here, roughly $200\text{ mas}$ in the image plane, the dust continuum emission from the Cosmic Eyelash is remarkably smooth, not clumpy.

Spatially resolved analysis performed at the positions of the clumps identified by Swinbank et al. (2010), which we have shown here to be spurious, e.g. the work presented by Swinbank et al. (2011); Danielson et al. (2011, 2013) and Thomson et al. (2015), must be viewed in this context. The clumpy structure presented by Swinbank et al. (2010) is believed to have been generated by applying the CLEAN algorithm to noisy long-baseline SMA data, amplifying features with low signal-to-noise ratios (SNRs), where

$^{3}$ The SMA 345-GHz (rest-frame 260 $\mu$m) image of Swinbank et al. (2010) had an r.m.s. noise level of $2.1\text{ mJy beam}^{-1}$ ($0.33 \times 0.21\text{ arcsec}^2$, PA $= 15^\circ$).
the remarkable symmetry of the resulting structure about the likely caustic lent credibility to a clumpy morphology that we show here to be spurious. Similarities between the molecular gas morphology presented by Swinbank et al. (2011) and the spurious continuum clumps was the result of low SNR, as illustrated by the simulations of Hodge et al. (2016), which showed that high-resolution low-SNR interferometric observations yield a clumpy distribution when there are no clumps. Faced with such data, the lesson here is that an analysis like that of Hodge et al. should always be undertaken, to gauge the reality of the clumps.

4 LENS MODELING

We have produced an updated version of the parametric mass model of the MACS J2135−01 cluster core described in Swinbank et al. (2010) using LENSTOOL4 (Jullo & Kneib 2009). We take the centroids of the ALMA image pair in Figs 1–2 as constraints.

We have used this lensing model to derive a parametric model of the source morphology at the origin of the continuum emission. We took a forward-model approach, assuming a Sérsic profile for the source, convolving by the ALMA beam and re-gridding to the same pixel grid in the image plane. The source parameters (centroid, PA, axis ratio and FWHM) were optimised while keeping the mass model fixed. Because of a small mis-match in the lens model,5 to reproduce both images simultaneously we performed the fit on each image independently, using the variations in the recovered parameters as an estimate of systematic errors due to the lens model.

The best source parameters with a single Sérsic profile reproduced the observed configurations well, with significant (> 5σ) residuals near the core of each image, symmetrical about the critical line. Adopting a more complex parameterised source, as is becoming routine with high-fidelity ALMA data (e.g. Rujopakarn et al. 2019) — this time comprising two independent Sérsic profiles, as might be expected for a merger-induced dusty starburst (Engel et al. 2010) or for a star-forming disk with a central starburst — the resulting best-fit source parameters gave two components lying very close in central position (within 0.01 arcsec or ≈ 80 pc in the source plane), but having large differences in Sérsic index and effective radii. The first one was rather extended (R_e ∼ 4.4 kpc) while the second one was brighter and more compact (R_e ∼ 1.2 kpc), with a small Sérsic index in both cases (n ∼ 0.5, so at the low end of the range found by Hodge et al. 2016, but consistent, as are the effective radii). Table 2 shows the best-fit parameters for each component.

Fig. 3 presents our best ALMA continuum image of the Cosmic Eyelash (Band 7, 303.9 GHz) alongside the respective best-fit source- and image-plane models, and residuals for the two-component Sérsic fit, where the observed map and the model are plotted with the same linear scaling (from zero to the peak observed flux density) as the residuals.

We found no mirrored sub-structure in the residual map and a brightest peak of 260 μJy, roughly 10σ above the noise; the deepest negative peaks reach 360 μJy which suggests — along with the lack of mirroring — that the sub-structure we see is not real. We followed the approach of Walter et al. (2016) to assess the fidelity of the residual peaks as a function of SNR, albeit needing to adopt large SNR bins, searching for both positive and negative peaks. We found no reliable candidates, even at 10σ: the fidelity of the brightest peaks was never better than 50 per cent. The residual peaks are all approximately consistent with the size of the synthesised beam, i.e. they are unresolved down to ≈ 80 pc in the source plane6 along the major axis. If we scale the maximum positive residual, which is magnified by roughly 8x and 1.6× along the major and minor axes, to the well-sampled SED of the Cosmic Eyelash, we find that its rest-frame 8–1000–μm luminosity cannot exceed 24 × 10^9 L_{⊙}. Adopting the traditional conversion from L_{IR} to SFR (e.g. Kennicutt & Evans 2012) — noting that recent evidence for a top-heavy stellar initial mass function in starbursts (Zhang et al. 2018b; Schneider et al. 2018; Motte et al. 2018, cf. Romano et al. 2019) would reduce these SFR limits significantly — then corresponds to a maximum ‘clump SFR’ of 2.6 M_⊙ yr^{-1}, around 1 per cent of the total for the Cosmic Eyelash, at the low end of the range of SFRs reported for clumps in star-forming galaxies at z ∼ 1–3 (e.g. Zanella et al. 2019) and consistent with the values reported via Hα observations of strongly lensed galaxies at 1 < z < 4

4 https://projets.lam.fr/projects/lenstool/wiki
5 With our parametric model for the cluster- and galaxy-scale mass components, the two images are reproduced with a small (∼ 0.02 arcsec) offset, such that sending both images back to the source plane yields a small mis-match in position.

6 Magnification varies spatially across the image plane, ranging from 3–13× along the major axis (mean, ∼ 10×), and ∼ 1.6× along the minor axis.

Figure 3. Left: Our most sensitive ALMA image of the Cosmic Eyelash, with the finest angular resolution, at 303.9 GHz, from the third panel of Fig. 2. Contours are plotted at −12, −6, −3, 3, 6, 12 ... or. Middle left and right: source- and image-plane models, respectively — see §4 — where the two best-fitting Sérsic profiles are contoured separately (green and blue) in the image plane, and the source-plane panel is 11.5 kpc across. Right: residuals, plotted with the same greyscale range and contours as the observed data and image-plane model. The synthesised beam is shown, lower right. Adopting the criteria of Walter et al. (2016) to assess the fidelity of the residual peaks, we find no reliable structure in the residual map.
5 SUMMARY

We present sensitive, high-spatial-resolution ALMA continuum imaging of the Cosmic Eyelash, at $z = 2.3$, which has been cited extensively as an example of where the interstellar medium exhibits obvious, pronounced clumps, with spatial scales of $\approx 100\, \text{pc}$, and where these clumps are cited regularly as circumstantial evidence that the blue clumps observed in UV-optical images of many $z = 2$–$3$ galaxies are important sites of ongoing star formation, with significant masses of stars and gas.

Our images reveal that the dust continuum emission from the Cosmic Eyelash is smoothly distributed and can be reproduced using two coincident Sérsic profiles with effective radii, 1.2 and 4.4 kpc, with no evidence of significant star-forming clumps down to a spatial scale of $\approx 80\, \text{pc}$, with rest-frame 8–1000-$\mu$m luminosities below $24 \times 10^{10} L_{\odot}$ and individual SFRs no higher than 1 per cent of the total, so $< 2.6\, M_{\odot}\, \text{yr}^{-1}$.
