Abstract

The use of stable isotope enrichment to mark mosquitoes has provided a tool to study the biology of vector species. In this study, we evaluated isotopic marking of Aedes aegypti (L.) (Diptera: Culicidae) in a laboratory setting. We determined the optimal dosage for marking adult Ae. aegypti mosquitoes with 13C and 15N. Additionally, Ae. aegypti mosquitoes were single and dually marked with 13C and 15N for up to 60 d postemergence without changes to adult body size or transgenerational marking. This report adds to the growing literature that explores the use of alternative marking methods for ecological and vector biology studies.

Key Words: Aedes aegypti, stable isotope, marker retention, mark-capture study, dispersal

Materials and Methods

We used Ae. aegypti mosquitoes from the Liverpool strain to evaluate the effects of single and dual isotopic enrichment of a hay-infusion larval habitat on male and female adults.

Isotopic Enrichment of Larval Habitat

In order to simulate a breeding site, plastic trays (34.3 x 25.4 x 3.8 cm of 3 liters) were prepared 1 wk prior to eclosion of mosquito eggs by adding 1 g of hay/liter of water, 0.002 g/liter of 13C and/or 15N (Hamer et al. 2012). Initial experiments combining isotopes and eggs on the same day yielded low enrichment (S. M. Garcia-Luna, J. G. Juarez and G. L. Hamer, unpublished data). Trays were placed into an environmental chamber set up to 28°C and a photoperiod of 12:12 light-dark hours to allow for microbial communities to develop. Two-hundred eggs per tray were added and followed until pupation, with the exception of the dose experiment on which 50 eggs per dose were used. When larvae reached L3, an additional 0.5 g of grounded fish food (TetraMin, Tetra, Germany) was added per tray as a nutrition supplement. Pupae were collected and placed in 100 ml plastic cups inside a BugDorm-1 (MegaView Science Co., Ltd., Taiwan). Adults were offered 10% sucrose solution ad libitum, which was changed weekly. Three individuals per treatment by experiment were collected into individual 1.7 ml microcentrifuge tubes.
and stored at −80°C until further processing. Control samples were reared as previously described without the addition of stable isotopes.

**Single and Dual Isotope Marking**

Mosquitoes were reared in either 0.002 g/liter of 13C-labeled glucose (U-13C, 99% atom%; Cambridge Isotope Laboratories, Inc., Andover, MA), 0.002 g/liter of 15N-labeled potassium nitrate (KNO3, 15N, 99% atom%; Cambridge Isotope Laboratories, Inc.) (Hamer et al. 2012) or a combination of both for the dual isotopic label (1:1 ratio) treatment. We tested if mosquito sex (male and female) and the time after adult emergence had an effect on the δ13C and δ15N by sampling adult mosquitoes at 7, 14, 21, 32, 39, and 60 d postemergence (dpe). We also evaluated three isotopic doses of 13C by hatching and rearing Ae. aegypti mosquitoes at concentrations of 0.001, 0.00075, and 0.00035 g/liter. We assessed the potential for transgenerational marking by allowing 3–5-d-old 13C-marked male (n = 50) and female (n = 50) mosquitoes to mate and produce offspring that were tested upon adult emergence.

In order to determine the effects of stable isotope enrichment on adult male body size, wing length measurements (n = 15 males/treatment) were taken. Subsequently, we evaluated if the addition of 400 µl of an artificial diet made of a 2% solution of desiccated and defatted liver powder (Bio-Serv, Flemington, NJ) and brewer’s yeast hydrolysate (Bio-Serv) at a ratio of 3:2 (which we will refer as LP) during egg eclosion, would influence δ13C and δ15N.

**Sample Processing and Analysis**

Samples were analyzed for isotopic marking at the Texas A&M University Stable Isotope Geosciences Facility using a Thermo Fisher Scientific Delta V Advantage with Flash EA Isolink attached to a ThermoFinnigan Conflo IV isotope ratio mass spectrometer as previously described (McDermott et al. 2019). Individual adult mosquitoes were placed in tin capsules in a 96-well plate. Mosquitoes were dried at 50°C for 24 h, and capsules were then crimped shut (Medeiros et al. 2017). δ13C (measurement of the ratio of stable isotopes 13C: 12C) versus Vienna Pee Dee Belemnite (VPDB) and δ15N (measurement of the ratio of stable isotopes 15N: 14N) versus air ([Rsample/Rstandard]×1,000) (IAEA 1995) values for each pool were recorded, regardless of isotope treatment. Differences in the mean δ13C or δ15N by treatment were analyzed using a two-sample t-test. Wing length was analyzed by using a nonparametric comparison (due to non-normality of data) using Dunn’s test with control for joint ranking. Normality was evaluated using the Shapiro Wilk test on the residuals.

**Results and Discussion**

We did not observe a difference in the δ values between male and female Ae. aegypti for either δ13C (m = 185, f = 193, t = 0.29, P = 0.7) or δ15N (m = 5284, f = 5322, t = 0.29, P = 0.7; Fig. 1). The persistence of single and dual marking over time was evaluated up to 60 dpe. The δ-values showed that single (δ13C: dpe 60 = 15.31 ± 0.31; δ15N: dpe 60 = 1081.41 ± 100.30) and dual (δ13C: dpe 60 = 9.05 ± 4.54; δ15N: dpe 60 = 996.93 ± 116.61) marking persist over time, at least under our laboratory experimental setting, and that it can be effectively measured if single or dual marking is carried out (Fig. 2). We did not detect a statistical difference when comparing the mean concentration of single or dual marking throughout the study, with the exception of δ13C for 14 (δ13C = 17.4, δ13C+15N = 8.08, t = −3.1, P = 0.02), 32 (δ13C = 10.4, δ13C+15N = 5.3, t = −2.57, P = 0.04) and 60 d postadult emergence (δ13C = 15.3, δ13C+15N = 9.1, t = −2.8, P = 0.03). This reduction for δ13C during the dual marking could be related to differential assimilation of carbon and nitrogen under different relative abundances of these elements. For example, in the presence of elevated nitrogen under the dual marking treatment, the larvae or larval diet could have assimilated less carbon.

When evaluating the three concentrations of 13C, we observed a significantly higher δ13C in comparison to the control (−18.32 ± 0.49; Fig. 3). This confirms that even at the lower tested dose (0.00035 g/liter) an effective marking can be detected (11.99 ± 9.92), allowing for lower concentrations to be used for enrichment purposes. To evaluate the potential for transgenerational marking, adult males and males with an average δ13C of 10.91 ± 7.9 produced progeny with values of −16.62 ± 0.29 for females and −17.60 ± 0.28 for males, demonstrating no transfer of 13C marking to F1 eggs (data not shown).

We assessed the effect of single and dual larval diet isotopic enrichment on the wing length (mm) of adult male Ae. aegypti. Males that had dual marking showed a statistically shorter wing length than the control males (control = 2.24 ± 0.19, dual = 2.08 ± 0.07, Z = −3.26, P = 0.003). When comparing the control to single isotopic marking with 13C (2.14 ± 0.05mm) and 15N (2.30 ± 0.14) no statistical difference was observed. However, wing length of our artificially fed males were all lower than the average 2.64 mm of field collected ones (Nasci 1986). This suggest that the larval environment relying on the natural microbiota provided by the hay infusion and the addition of fish food at the L3 stage provided insufficient nutrition for developing larvae. In light of this, we evaluated the addition of the artificial diet as supplemental nutrition following the previous procedures. We were able to detect the isotopic marking of males (δ13C: 389.98 ± 15.01; δ15N: 5,531.84 ± 70.33) and females (δ13C: 5,694.16 ± 164.62) when artificial food was added. We were unable to collect sufficient females for the 13C isotopic marking. This demonstrates that the early addition of artificial food for nutrition allowed the bioaccumulation of stable isotopes into adult structural tissues to persist.

This study documents that similar protocols to isotopically mark Culex, Anopheles, and other species of Aedes mosquitoes also apply to Ae. aegypti. This study extends prior laboratory marking studies
by showing very little decay over the 60-d period as adults (Hamer et al. 2012). The lack of transgenerational marking of progeny improves the utility of using stable isotopes in a mark-capture study design. As a container species mosquito and as a vector responsible for 96 million cases of dengue each year (Bhatt et al. 2013), the use of stable isotope marking offers a valuable tool to study the biomics of *Ae. aegypti*.
