Case Report

Conversion phenomenon during the induction period of general anesthesia
-A case report-

Conversion disorder is characterized as psychological symptoms such as somatization and emotional distress, but there is no abnormal electrical signal in the brain. We report a patient who appeared conversion disorder during the induction period of general anesthesia. A 45-year-old woman was planned for arthroscopic knee meniscectomy. In the operating room, she appeared stable, but she said extremely nervous in this situation. Before propofol injection for induction of anesthesia, we injected 1% lidocaine 50 mg iv for pain relief. Immediately after injection, she showed general seizure-like activity and then tonic-rigid muscle tone, dyspnea with periodic breathing without cyanosis, and clouding of consciousness. The operation was delayed, and she was examined by neurosurgeon and psychiatrist. She was diagnosed as suffering with conversion disorder and she was without brain abnormalities on the magnetic resonance imaging. Her condition improved after anti-depressant medication and supportive psychotherapy. She underwent uneventful knee surgery 40 days later. (Korean J Anesthesiol 2010; 59: 210-213)

Key Words: Anesthesia, Conversion, Distress, Psychotherapy.

Many patients experience preoperative anxiety prior to surgery, which can sometimes leads to psychological problems. Irritating matters are those concerned with death, nausea, vomiting, pain, urinary retention, postoperative confusion, nerve injury, and hypothermia [1]. The use of anxiolytic medication and counseling techniques have been shown to stabilize a patient's mood. Therefore, appropriate steps and careful assessment of mood status, intervention, and premedication can decrease the level of upsetting preoperative psychological conditions. Conversion disorder, once understood as hysteria, has a morbidity rate of 0.2% in the general population and a 5% rate of occurrence in general hospitals. However, in some recent studies, life-long morbidity rates have been found to be as high as 33% [2]. We report a patient who had previously undiagnosed anxiety, depressive disorder, and exhibited conversion phenomenon immediately after the injection of 1% lidocaine 50 mg for anesthetic induction.

Case Report

A 45-year-old woman was scheduled for arthroscopic left knee meniscectomy. Her preoperative medical history, hematological, and biochemical findings were within normal limits. Her weight, height, and body temperature were 80 kg, 158 cm, 36.5°C, respectively. Upon arrival to the operating room, she appeared stable, but expressed fear and worry. Her blood pressure was 160/80 mmHg, heart rate 80 beats/min, and pulse oximetry saturation 100%. Prior to propofol injection, 1% lidocaine 50 mg was intravenously injected for pain control. Subsequently, she suddenly expressed hyperventilation, seizure-like activity, then tonic-rigid muscle tone, dyspnea with periodic breathing (not involving cyanosis), profound sweating, and clouding of consciousness. She was ventilated with 100% oxygen 7 L/min by mask. Her pupillary light reflex was normal, and clouding of consciousness. She was ventilated with 100% oxygen 7 L/min by mask. Her pupillary light reflex was normal, and clouding of consciousness. She was ventilated with 100% oxygen 7 L/min by mask. Her pupillary light reflex was normal, and clouding of consciousness. She was ventilated with 100% oxygen 7 L/min by mask. Her pupillary light reflex was normal, and clouding of consciousness. She was ventilated with 100% oxygen 7 L/min by mask. Her pupillary light reflex was normal, and clouding of consciousness. She was ventilated with 100%

Discussion

Patients attempt to escape from stressful circumstances in order to reduce anxiety, to ensure self protection, and to gain others’ attention. Preoperative psychiatric evaluation could reduce anxiety problems prior to anesthesia, and thus, lead to improved outcomes [3].

Conversion disorder involves unbearable psychological symptoms to physical things as to resolve. Symptoms usually involve unconscious motor or sensory impairment and are not related to organic pathology [2,4]. Further, it is more frequent in women than in men. The onset of this disease is early adulthood, and tends to occur more frequently those living in rural areas, those associated with a lower socioeconomic class, and in less educated individuals [2]. In the past, our patient had experienced financial problems as well as major depressive disorder, which could be another causative factor for this disease.

The diagnosis of conversion disorder depends on psychological conditions that are not intentionally produced, and not on neurological or medical conditions [2]. Prior to diagnosis, physical evaluation, past medical history, and laboratory findings should be evaluated to exclude other diseases. Additionally, differential diagnosis excluding other organic etiological factors is important. Further, organic-related symptoms are physical stress-related, can occur at any time, and presenting systemic symptoms [4].

There are only a few reports of conversion related to anesthesia. In the operating room, conditions such as hypoglycemia, hypotension, hypothermia, hypercarbia, alkalosis, acidosis, electrolyte imbalance, and bleeding can delay awakening and thus, interfere with diagnosing conditions that are psychologically-induced [2,5]. Although conversion-evoked seizure may appear similar to episodes of true neurologically-based seizure, those induced by conversion are not caused by an abnormal electrical discharges, transient ischemic attack, or hypoglycemia. In this case, the patient had no organic system damage, and further, her emotional stress led to chronic depression, which occurred only during times of emotional instability. The lack of skin cyanosis, retention of the pupillary light reflex, and negative sign on MRI indicated that her condition had not be of neurological origin [6]. We were unable to evaluate the patient’s electroencephalography due to her refusal. After evaluation from a psychiatrist, it was determined that the patient’s condition had originated from conversion.
In the course of regional anesthesia, local anesthetics are used. At low concentrations in the blood, they serve to decrease cerebral blood flow, metabolism, and electrical activity, whereas at high concentrations, they act as proconvulsants by lowering seizure threshold. For example, lidocaine induces seizure by blocking brain inhibitory neurons in the amygdala and hippocampus [7]. Therefore, if a large amount of local agent is administered in regional anesthesia, patients can be at increased risk of CNS, cardiac toxicity problems. However, in this case, a total of only 50 mg of 1% lidocaine was used, and therefore, the proconvulsant activity of lidocaine can be ruled out as the cause of the convulsion.

Factors associated with a good prognosis upon diagnosis of conversion disorder include being male, an acute onset, a short duration of symptoms, and a premorbid psychiatric diagnosis. Predictors of a poor prognosis include subclinical personality pathology, coexisting medical illness, and a poor perception of their own wellbeing [2]. In this case, the patient’s disease interval period was three years, which is relatively long. Also, other mood disorders coexisted; however, her psychological conditions were well managed and symptoms were relieved through an outpatient clinic drug treatment program.

The management of conversion disorder involves a psychiatric examination and neurological assessment, followed by an explanation of the problem with successful communication and subsequent cognitive behavioral therapy. Additionally, preoperative education can lead to a better understanding of anesthesia and can thereby, decrease the related anxiety [8,9]. Further, preoperative medications such as alprazolam and midazolam can also reduce anxiety in preoperative patients [10]. In this case, we anesthetized the patient using midazolam 3.0 mg immediately after her arrival to the operating room in order to decrease anxiety. A combination of psychotherapy, antidepressants, and the adherence to a multidisciplinary approach are beneficial in the resolution of this disease.

There has been nothing known regarding conversion disorder with respect to general and regional anesthesia. Also, there have been no case reports, such as the one presented here, of conversion phenomenon during anesthesia induction. Haden did report one case of an anxious 12-year-old girl whose tongue had been paralyzed after general anaesthesia for a dental procedure. Her symptom was resolved after counseling [11]. In another case, a spinal anesthetized patient was managed through propofol sedation in stressful arthroscopic surgical situation. After consulting with the pediatrician, it was concluded that preoperative stressful conditions had resulted in conversion disorder [12]. Further, Yokoyama et al. [13] reported a case of monoplegia conversion disorder after spinal anesthesia. In this patient, a psychic stressful family problem was the causative factor. Another case was reported involving a foot dorsiflexion defect after epidural anesthesia in an individual who had previously suffered from depressive mood disorder [14]. Clarke and Clarke [15] reported a 10-year-old girl with instant double vision problems after a dental block which was conclude to have originated from a fearful mind regarding the dental procedure and later disappeared after reassurance. It is vital to be prepared for any conversion circumstances using basic principles and anxiety-reducing sedation therapy regardless of whether general or regional anesthesia is employed. It is suggested that we sometimes miss psychological problems in patients and therefore, misdiagnose the problem in the operating room.

In conclusion, when patients present a sudden loss of sensory or abnormal motor function in the operating room, we should consider not only organic disease, but also conversion phenomenon. Careful evaluation of a patient’s medical history, mental status, physical findings, and laboratory tests must occur. Overall, there is a need for releasing psychogenic stress during the preoperative period of anesthesia.
