ABSTRACT
We study the abundance of satellite galaxies as a function of primary stellar mass using the Sloan Digital Sky Survey/Data Release 7 (SDSS/DR7) spectroscopic catalogue. In contrast with previous studies, which focused mainly on bright primaries, our central galaxies span a wide range of stellar mass, $10^{7.5} \leq M^{*}_{\text{pri}}/M_{\odot} \leq 10^{11}$, from dwarfs to central cluster galaxies. Our analysis confirms that the average number of satellites around bright primaries, when expressed in terms of satellite-to-primary stellar mass ratio ($m_{\text{sat}}^{*}/M^{*}_{\text{pri}}$), is a strong function of $M^{*}_{\text{pri}}$. On the other hand, satellite abundance is largely independent of primary mass for dwarf primaries ($M^{*}_{\text{pri}} < 10^{10} M_{\odot}$). These results are consistent with galaxy formation models in the $\Lambda$ cold dark matter ($\Lambda$CDM) scenario. We find excellent agreement between SDSS data and semianalytic mock galaxy catalogues constructed from the Millennium-II Simulation. Satellite galaxies trace dark matter substructure in $\Lambda$CDM, so satellite abundance reflects the dependence on halo mass, $M_{200}$, of both substructure and galaxy stellar mass ($M^{*}$). Since dark matter substructure is almost scale free, the dependence of satellite abundance on primary mass results solely from the well-defined characteristic mass in the galaxy mass-halo mass relation. On dwarf galaxy scales, where models predict a power-law scaling, $M_{\ast} \propto M_{200}^{2.5}$, similarity is preserved and satellite abundance is independent of primary mass. For primaries brighter than the characteristic mass of the $M_{\ast} - M_{200}$ relation, satellite abundance increases strongly with primary mass. Our results provide strong support for the steep, approximately power-law dependence of dwarf galaxy mass on halo mass envisioned in $\Lambda$CDM galaxy formation models.

Key words: galaxies: dwarf – galaxies: formation – galaxies: haloes.

1 INTRODUCTION

Matching the galaxy luminosity function in the $\Lambda$ cold dark matter ($\Lambda$CDM) scenario requires that the stellar mass of galaxies, $M_{\ast}$, should vary strongly with the virial mass, $M_{200}$, of their surrounding dark matter haloes. This exercise implies that the ‘efficiency’ of galaxy formation, as measured by the ratio $M_{\ast}/M_{200}$, decreases steadily towards both smaller and larger masses from a maximum at $M_{200} \sim 10^{12} M_{\odot}$ (Yang, Mo & van den Bosch 2003; Vale & Ostriker 2004; Shankar et al. 2006; Zheng, Coil & Zehavi 2007; Behroozi, Conroy & Wechsler 2010; Guo et al. 2010, 2011; Kravtsov 2010; Moster et al. 2010). On the scale of dwarf galaxies ($M_{\ast} < 10^{11} M_{\odot}$), these models require a near power-law dependence, $M_{\ast} \propto M_{200}^{\gamma}$, in order to reproduce observations of faint objects (however, see Behroozi, Wechsler & Conroy 2012). Such a steep $M_{\ast} - M_{200}$ relation implies that dwarfs differing by as much as three decades in stellar mass (e.g. from the Fornax dwarf spheroidal to the Large Magellanic Cloud) inhabit haloes spanning just over one decade in virial mass. Furthermore, very few galaxies exceeding $10^{9} M_{\odot}$ are expected to have haloes with virial masses below $10^{10} M_{\odot}$ (Ferrero et al. 2011).

These predictions have been recently challenged by a series of observations, including (i) the lack of a characteristic velocity at the faint-mass end of blind H I surveys (expected if most dwarfs live in similar haloes, Zwaan, Meyer & Staveley-Smith 2010; Papastergis et al. 2011); and (ii) the low virial mass (substantially below $10^{10} M_{\odot}$) inferred from dynamical data for the dwarf spheroidal companions of the Milky Way (Boylan-Kolchin,
Bullock & Kaplinghat (2012) and for nearby dwarf irregulars (Ferrero et al. 2011). The evidence, however, is indirect, since halo masses are estimated by extrapolating data that probe only the inner few kiloparsecs, where most baryons reside.

We explore here the possibility of using satellite galaxies to help constrain the virial masses of dwarf galaxies. The orbital motions of satellite companions have often been used to estimate halo masses (see, e.g., Zaritsky et al. 1997; Erickson, Gottesman & Hunter 1999; McKay et al. 2002; Prada et al. 2003; van den Bosch et al. 2004; Brainerd 2005; Conroy et al. 2007; Wojtak & Mamon 2012), but this work has largely been restricted to systems similar to or brighter than the Milky Way. This is partly due to the difficulties in obtaining redshifts for faint objects. In addition, satellite companions are less common around dwarf galaxies than around larger systems: the number of satellites brighter than a certain fraction of the primary luminosity, N (> L*/Lm), declines strongly towards fainter primaries (e.g. Guo et al. 2011; Wang & White 2012). The dwarf galaxy associations do exist, but only a handful have been observed (e.g. Tully et al. 2006).

In ΛCDM, where satellite galaxies are thought to trace the substructure of CDM haloes, satellite systems are expected around all central galaxies, regardless of luminosity. The number of satellites, and their dependence on primary mass, should just reflect the abundance of substructure modulated by the dependence of galaxy formation efficiency on halo mass.

The substructure abundance has been studied extensively through numerical simulations and shown to be nearly invariant with halo mass when expressed as a function of satellite mass normalized to that of the host (Moore et al. 1999; Gao et al. 2004; Kravtsov et al. 2004; Conroy et al. 2007; Wojtak & Mamon 2012). This result, together with the strict constraints on galaxy formation efficiency mentioned above, imply that satellite number counts provide useful information on the halo mass of dwarf galaxies. In particular, the near self-similarity of cold dark matter haloes provides an instructive test: if satellite galaxies trace substructure, then the abundance of luminous satellites should also be scale free on scales where galaxy mass and halo mass are related by a power law.

We explore these issues here by identifying primary satellite systems in galaxy catalogues constructed from the SDSS and by comparing them with predictions from a semianalytic mock galaxy catalogue based on the Millennium Simulations. The plan for this paper is as follows. Section 2 describes briefly the observational and model data sets while Section 3 presents our main results. We summarize our main conclusions in Section 4.

2 DATA AND CATALOGUES

2.1 Satellite and primary galaxies in SDSS/DR7

We select primary galaxies spanning a wide range of stellar mass, 7.5 ≤ log(M*/M⊙) ≤ 11, from the spectroscopic New York University Value Added Galaxy Catalogue (NYU-VAGC). This catalogue was built on the basis of the seventh data release of the Sloan Digital Sky Survey/Data Release 7 (SDSS/DR7; Blanton et al. 2005; Abazajian et al. 2009). The stellar masses are taken directly from the NYU-VAGC catalogue and are estimated by fitting stellar population synthesis models to the k-corrected galaxy colours. They assume a Chabrier (2003) initial mass function.

We ensure isolation by imposing two conditions: (i) each primary must be the brightest of all objects projected within its virial radius with line-of-sight velocities differing by less than three times the corresponding virial velocity and (ii) no primary can be located within the virial radius of a more massive system. Virial quantities are inferred from the stellar mass, assuming the abundance–matching M*−M200 relation of Guo et al. (2010) and cosmological parameters consistent with Wilkinson Microwave Anisotropy Probe (WMAP1) results Ωm = 0.75, Ωb = 0.25 and H0 = 73 km s⁻¹⁻¹ (Spergel et al. 2003). Fainter galaxies within a projected distance rp < r200 and a line-of-sight velocity difference ∆Vlos < 3V200 are then classified as satellites (see Section 2.2). We have checked that our results are not sensitive to variations by the factors of a few in these thresholds, nor to the addition of 0.2–0.35 dex scatter to the M*−M200 relation.

We apply volume and edge corrections to our sample in the same way as Wang & White (2012). Completeness for SDSS spectroscopic data is estimated to be ~90 per cent for apparent r-band magnitudes brighter than m_r = 17.7 (Blanton et al. 2005). This limit applies to the satellite and primary galaxies independently. However, satellites are fainter than their centrals, having an absolute magnitude difference ΔM* = M*/M⊙. This means that the effective volume where satellites of a given ΔM* are (almost) complete varies strongly with M*, or equivalently with primary mass. For instance, satellites about a magnitude fainter than their hosts will have M*/M⊙ ∼ −20.5 and −15.2 for primaries with stellar masses in the ranges 10.5 < log (M*/M⊙) < 11 and 7.5 < log (M*/M⊙) < 8, respectively. In our sample, the limiting distance where satellites can be found with ΔM* = 1 is roughly 320 kpc for primaries with 10.5 < log (M*/M⊙) < 11. This halves for primaries with M* ∼ 10^{10} M⊙ and drops to 35 Mpc for centrals with 7.5 < log (M*/M⊙) < 8. Despite the smaller volume surveyed for low mass galaxies, there are still enough galaxies to probe the satellite population of even the faintest primaries we considered.

One might think that the detection of faint objects would be aided by selecting satellites from the photometric catalogue, which is complete down to ~4 mag fainter than the spectroscopic sample. This requires the stacking of primary galaxies and a statistical background subtraction in order to identify the excess count corresponding to satellites (Lorimer et al. 1994; Guo et al. 2011; Lares, Lambas & Domínguez 2011; Liu et al. 2011; Nierenberg et al. 2011; Strigari & Wechsler 2012; Wang & White 2012). However, the signal-to-noise ratio to carry out this subtraction is too low for our faint primaries (M* < 10^{9} M⊙). Our sample is then selected purely from the spectroscopic catalogue. We discuss briefly possible biases affecting faint, low surface brightness companions in Section 3.

2.2 Satellite and primary galaxies in the semianalytic model

We compare our SDSS results with the semianalytic catalogue of Guo et al. (2011), based on the dark matter only Millennium-II Simulation (hereafter MS-II, Boylan-Kolchin, Besla & Hernquist 2011). The model parameters are carefully tuned to reproduce the observed abundance of low-redshift galaxies over five orders of magnitude in stellar mass and 9 mag in luminosity. The semianalytic data contain full 3D velocity and positional information for all galaxies and thus enables the evaluation of potential biases that may be induced by the limited (projected) data available in observational surveys.

Figs 1 and 9 of Guo et al. (2011) show that predictions for galaxy mass are reliable in simulated haloes resolved with at least ~200–300 dark matter particles. This corresponds roughly to M200 ∼ 2 × 10^{9} M⊙ and M* ∼ 10^{6} M⊙ in MS-II. We therefore consider only galaxies with M* ≥ 10^{6} M⊙ in the analysis below.
Galaxies in the semianalytic catalogue inhabit dark matter haloes and subhaloes identified using the SUBFIND group-finder algorithm (Springel, Yoshida & White 2001). Primary galaxies are the central objects of each halo; all other galaxies within the virial radius are considered satellites. The catalogue also includes ‘orphan’ galaxies whose subhaloes have been disrupted due to numerical resolution effects. The catalogue contains more than 157 000 primary galaxies in the mass range $7 \leq \log(M_*/M_\odot) \leq 12$.

The semianalytic data can be ‘projected’ to mimic the same satellite identification algorithm used for SDSS data (see, e.g., Wang & White 2012 for details). Note that, because of the different identification criteria applied, the projected satellite and primary samples selected from the mock catalogue differ from the 3D samples (where we use information about the condition as central/satellite object from the SUBFIND catalogues). This enables us to calibrate the parameters of the identification procedure in order to minimize the contribution of foreground and background objects in our primary/satellite sample.

Fig. 1 shows the distributions of projected distance ($r_p$, shown in black) and line-of-sight velocity difference ($\Delta V_{\text{l.o.s.}}$, shown in red) between primaries and ‘true’ satellites, grouped in several bins of primary stellar mass. The primaries in each bin span a range of virial masses given by the $M_\ast - M_{200}$ relation and its scatter. For each panel, a horizontal line indicates the minimum and maximum virial radius/velocity of the host haloes contributing to that bin. All histograms peak approximately at the average virial radius and virial velocity of host haloes in the subsample, indicated by the vertical dotted line.

Although by definition $r_p < r_p^{\text{max}} = r_{200}$, the upper bound of the velocity difference is less clear, as the escape velocity typically exceeds the virial velocity of a halo substantially in the inner regions. The red histograms in Fig. 1 suggest that the large majority of true satellites have line-of-sight velocities that differ from their primaries by less than $\sim 3V_{200}$. These considerations justify the choices $r_p^{\text{max}} = r_{200}$ and $\Delta V_{\text{l.o.s.}}^{\text{max}} = 3V_{200}$ made to identify satellite/primary systems in the observational sample (Section 2.1).

### 3 RESULTS

As discussed in Section 1, the galaxy–halo mass relation is expected to leave a clear imprint on the abundance of satellites galaxies as a function of primary stellar mass. We explore these ideas in Fig. 2 using the semianalytic catalogue described in Section 2.2.

Fig. 2 shows, as a function of satellite-to-primary mass ratio, the average number of satellites orbiting primaries of different mass in the semianalytic galaxy catalogue. Primaries are binned in logarithmic $M_\ast$ bins of 0.5 dex width; the central mass value is quoted in the legend. Satellites are identified in 3D, using the full position and velocity information available in the catalogue.

Fig. 2 shows clearly that the average number of satellites of binned mass functions becomes independent of the primary mass.
power-law scaling between galaxy and halo masses in these scales and is a prime prediction of the model testable by observation.

In order to take into account how projection effects and the presence of interlopers may affect this result, we repeat the analysis using only projected positions and line-of-sight velocities, as described in Section 2.2. This enables us to select primaries and satellites in identical ways for both model and observational data sets.

Fig. 3 shows, for the mock (left) and SDSS (right) samples, the average number of satellites with $r$-band magnitude difference equal to or smaller than $\Delta M = M_{\text{sat}} - M_{\text{pri}}$. This is not only the simplest observational analogue of the stellar mass ratio but also allows a more straightforward derivation of the completeness correction for the catalogue. The use of stellar masses would introduce extra uncertainties that would have to be compensated by more conservative surface brightness sensitivity become available.

The deblending of extended objects into multiple spurious ‘galaxies’ could potentially affect our results. As a sanity check, we have repeated the analysis of Fig. 3 using the NASA Sloan Atlas\(^2\) (NSA). This catalogue is based on SDSS-DR8 data but uses a different background subtraction technique that specifically improves the identification of galaxies over the original SDSS pipeline, especially for low-redshift extended objects (Blanton et al. 2011; Geha et al. 2012). This catalogue only includes galaxies with redshifts $z < 0.055$ and is almost complete for (model) $r$-band magnitudes $m_r < 17.2$. Once equivalent cuts are applied to our sample we find that the abundance of satellites in DR7 and NSA are consistent within their error bars, with a small upward offset of DR7 compared to NSA. This shift is negligible for $M_{\text{sat}} \geq 10^{10} M_\odot$ and less than a factor of $\sim 2$ for fainter primaries, which is comparable to the uncertainties estimated by bootstrap of the samples. Importantly, the apparent mass independence of satellite counts for primaries less massive than $M_{\text{sat}} = 10^{10} M_\odot$ is also found in the NSA sample.

\(^2\)http://www.nsatlas.org

---

**Figure 3.** Average number of satellites per primary with an $r$-band magnitude difference smaller or equal to $\Delta M = M_{\text{sat}} - M_{\text{pri}}$. Each curve corresponds to a given primary stellar mass range, as indicated by the labels. The left-hand panel is for mock data from the semianalytic catalogue. The primary/satellite galaxies are identified in projection, as outlined in Section 2.1. The error bars show uncertainties from 100 bootstrap resamplings. Note the lack of dependence on $M_{\text{sat}}$ for $M_{\text{sat}} < 10^{10} M_\odot$. Right: same but for galaxies in the SDSS/DR7 spectroscopic catalogue. As in the left-hand panel, isolated dwarfs with stellar mass $7.5 < \log(M_{\text{sat}}/M_\odot) < 10$ seem to populate similar dark matter haloes, $M_{200} \sim 10^{10} - 10^{11} M_\odot$ according to the simulations.
In addition to providing hints about the power-law nature of the $M_* - M_{200}$ relation at the low-mass end, satellite number counts can also help constrain its slope. Assuming that satellite and primary galaxies follow the same $M_* \propto M_{200}^{1.35}$ power-law relation and that the unevolved subhalo mass function is self-similar, as predicted by CDM, the abundance of faint satellites should scale roughly with $N(\mu) \propto \mu^{\alpha/\beta}$, where $\mu = m_{\text{sat}}/M_{\text{DM}}$. Note that this behaviour is only expected over the mass ranges where the substructure mass function is a power law, which typically requires $\mu \lesssim 0.1$ (e.g. Giocoli et al. 2008). This imposes an upper limit $\mu_* = 0.1^{0.4} \approx 0.003$ on the relative mass of the companions we expect $N(\mu) \propto \mu^{\alpha/\beta}$ to hold.

In the semianalytic model, $\alpha/\beta \sim 0.95/2.4 \sim 0.4$, which is roughly in agreement with the slope of the satellite mass function in Fig. 2 measured for low-mass companions $m_{\text{sat}}/M_{\text{DM}} \leq 0.003$. This relation is independent of $M_*$, provided that the simulation resolves satellites to differ by three or more orders of magnitude in stellar mass with respect to $M_{200}$. This, in our simulations, happens at $M_{\text{DM}} > 10^{13} M_\odot$. Interestingly, the scatter in stellar mass at fixed halo mass, which in the model is $\sim 0.35$ dex for the low-mass objects (Guo et al. 2011), does not seem to impact the slope derived from the simple arguments given previously. However, this would change if the scatter in the $M_* - M_{200}$ relation were strongly correlated to the halo mass. In our case this correlation is rather mild.

We conclude from Fig. 3 that the good agreement in shape, normalization and slope between SDSS primaries and the mock catalogue strongly favours a power-law relation with a steep slope $M_* \propto M_{200}^{1.35}$, between stellar mass and halo mass of dwarf galaxies. This agrees with predictions from the semianalytic model of Guo et al. (2011) and from extrapolations of abundance-matching studies (e.g. Behroozi et al. 2010; Guo et al. 2010; Moster et al. 2010).

4 DISCUSSION AND CONCLUSIONS

We study the abundance of satellites as a function of primary stellar mass in the SDSS. Using the SDSS/DR7 spectroscopic sample from the NYU-VAGC catalogue, we are able to extend previous studies to significantly fainter primaries, $M^{\text{DR}}_{\text{DM}} = [10^{7.5} - 10^{11}] M_\odot$. In agreement with previous work, we find that the abundance of satellites exceeding a given satellite-to-primary stellar mass ratio, $m_{\text{sat}}/M_*$, depends strongly on $M_*$ for bright primaries. On the other hand, the abundance of satellites around dwarf primaries, $M_*/M_\odot < 10^{10}$, is approximately independent of primary stellar mass.

These results are in excellent agreement with predictions of semianalytic models within ΛCDM. These trends arise from the mass invariance of substructure in CDM haloes and from the varying efficiency of galaxy formation as a function of halo mass. On dwarf galaxy scales, where the relation between galaxy mass and halo mass is well approximated by a steep power law, the invariance of satellite abundance with primary mass reflects directly the scale-free nature of substructure. Around bright galaxies the scaling between galaxy mass and halo mass deviates from a simple power law, leading to the observed strong increase of the satellite abundance with increasing primary mass.

Some caveats on the statements above need to be mentioned. The first relates to the definition of halo mass for a galaxy that has entered the virial radius of a larger object. The mass in subhalos is in general ill-defined, depending not only on the identification algorithm (Knebe et al. 2011), but also on time, due to tidal stripping (e.g. Tormen, Diaferio & Syer 1998; Klypin et al. 1999; Hayashi et al. 2003). The stellar mass, however, is more resilient to tidal effects and remains approximately constant after accretion on to the host (White & Rees 1978; Sales et al. 2007; Peñarrubia, Navarro & McConnachie 2008). Thus, for satellite galaxies, the virial mass at the moment of accretion is more closely related to the stellar mass than their present-day dark halo mass. Since the abundance of subhaloes according to their infall mass – termed the ‘unevolved’ subhalo mass function – is also independent of host halo mass when written as a function of the relative mass between satellite and host $m_{\text{sat}}/M_\text{DM}$ (e.g. Giocoli et al. 2008; Yang et al. 2011), the arguments given above remain valid.

The second caveat involves the possible dependence of the $M_* - M_{200}$ relation on redshift and, related to that, whether satellites and primaries follow the same relation between stellar mass and halo mass. Abundance matching models suggest that the link between the stellar mass and halo mass evolves weakly with redshift (Shankar et al. 2006; Conroy & Wechsler 2009; Wang & Jing 2010; Leauthaud et al. 2011; Behroozi, Wechsler & Conroy 2012; Moster, Naab & White 2012; Yang et al. 2012). Given that the surviving satellites are preferentially accreted at late times (e.g. Gao et al. 2004; Sales et al. 2007) the $M_* - M_{200}$ relation for satellites and centrals are expected to be similar. In particular, self-consistent semianalytical modelling of galaxies shows only small differences between the two (e.g. see fig. 9 of Guo et al. 2011).

We note that these arguments do not allow for stripping of the stars from satellites. Arguably, this could complicate the evolution. We note, however, that numerical models for dwarf galaxies suggest that once stellar stripping sets in, total disruption soon follows (Peñarrubia et al. 2008). We therefore expect partial stripping of stars to have minor effects in large statistical samples. On the other hand, several studies have suggested that accounting for total disruption of satellites is needed to match observations (e.g. Weimann et al. 2006; Kimm et al. 2009). We address this by comparing observational results with a semianalytic model that explicitly treats satellite disruption by tidal forces.

Under the assumption of a ΛCDM universe, the good agreement in shape and normalization between satellite counts in SDSS and those in the mock catalogue provides support for a steep stellar–halo mass relation for dwarfs, consistent with the $M_* \propto M_{200}^{1.35}$ predicted both by semianalytic models and by extrapolations of current abundance–matching analyses. More definitive constraints on the slope of the $M_* - M_{200}$ relation for dwarf galaxies may come from a robust determination of the slope of satellite abundances around isolated primaries in tandem with studies of the effect of scatter in the stellar mass–halo mass relation. Probing increasingly fainter companions in observational surveys of the surroundings of isolated dwarfs may prove crucial for this goal.
