Abstract: Natural products have a significant role in the development of new drugs, being relevant the pentacyclic triterpenes extracted from Olea europaea. Anticancer effect of uvaol, a natural triterpene, has been scarcely studied. The aim of this study was to understand the anticancer mechanism of uvaol in HepG2 cell line. Cytotoxicity results showed a selectivity effect of uvaol with higher influence in HepG2 than WRL68 cells used as control. Uvaol presented anti-migratory capacity in HepG2, supported by the morphological changes and higher HSP-60 expression. This compound also induced arrest in G0/G1 phase and an increase in apoptosis rate. These results are supported by decreased Bcl-2 expression and down-regulation of AKT/PI3K signaling pathway. A reduction in reactive oxygen species levels in HepG2 cells was observed. Altogether, results showed anti-proliferative and pro-apoptotic effect of uvaol on hepatocellular carcinoma, constituting an interesting challenge in the development of new treatments against this type of cancer.

Keywords: AKT/PI3K signaling pathway; apoptosis; human hepatocarcinoma HepG2 cells; migration activity; proliferation; oxidative stress; ROS level; uvaol

1. Introduction

Cancer is one of the leading causes of mortality worldwide, especially in developed countries on account of the aging of the population [1]. Liver cancer is the fifth most common type, as well as the second type of tumor that causes more deaths globally. Specifically, hepatocarcinoma (HCC) accounts for 90% of primary liver neoplasms, whose incidence increases progressively with ageing, according to the EASL (European Association for the Study of the Liver) [2].

Hepatocarcinogenesis is a process initiated by different external stimuli that induce genetic changes in hepatocytes or hepatic stem cells, which can cause alterations in the processes of proliferation and apoptosis, by dysfunctions in the cell cycle and its regulation, which eventually lead to tissue dysplasia and can cause a neoplasm [3]. In response to this DNA damage, different control points can be activated throughout the cell cycle phases. Among all the proteins that regulate this process, p53 stands out [4]. The blocking of the activity of protein kinases regulated by p53 produce
an inhibition of cell cycle progression due to arrest in G1 phase [5]. It is known that p53 is frequently mutated in HCC, blocking the correct role of this protein [6].

Another important pathway involved in hepatocarcinogenesis is that controlled by c-Myc proto-oncogene. The elements of the Myc proto-oncogenes family have a role as strong transcription factors of other proteins that take part in the control of cell differentiation and proliferation, oncogenesis and apoptosis [7]. Studies show that c-Myc is overexpressed in HCC comparing with healthy patients [8].

One of the main characteristics of tumor cells is their resistance to cell death, so the apoptosis process is one of the most studied pathways. This programmed cell death can occur through two pathways: the mitochondrial or intrinsic and the one that involves death receptors, also named extrinsic. In response to various external stimuli, the mitochondria increases its permeability, releasing apoptotic mediators, among which proteins from the Bcl-2 family and cytochrome c stand out [9].

It is well established that NADPH molecules are essential in anabolic processes related to membranogenesis as well as in nucleotide metabolism through ribose phosphate formation [10], and also plays a decisive role as a modulator of protein synthesis [11]. Therefore, the participation of NADPH in both metabolic aspects makes it especially important for growth and cell differentiation [12]. For these reasons, the regulation of NADPH levels is essential to understand the behavior of numerous physiological processes and, in this sense, nutritional conditions [13-16]; presence of triterpenes [17, 18]; and the redox state [19] modify significantly the levels of those reduction equivalents.

Reactive oxygen species (ROS) in non-pathological concentrations act as second messengers involved in several signal transduction pathways that regulate processes such as cell growth, proliferation and differentiation [20]. Therefore, cells have detoxification mechanisms that maintain a redox balance since, if this is altered, excessive production of ROS can lead to a situation of oxidative stress, which plays an important role in apoptosis and in the beginning of neoplastic processes. Within these detoxification mechanisms, several enzymes stand out, such as superoxide dismutase (SOD), catalase (CAT) or glutathione peroxidase (GPX) [21].

Some pharmaceutical compounds used to HCC treatment, such as Sorafenib, inhibite VEGF angiogenic factor and MAPK pathway [22]. Since the efficacy of current therapies is low when advanced stages of HCC are considered, it is necessary to seek alternative treatments that could offer better results [23]. Traditional medicine occupies an important place in the development of new drugs, since natural compounds are a recurring source of molecules with bioactive properties [24].

The Mediterranean diet presents olive oil as its main exponent, which is obtained from the fruit of the Olea europaea. Its consumption is associated with various health benefits [24], among which there is a lower incidence of cardiovascular diseases, a lower production of ROS and even a reduction in the risk of cancer [25-27]. These properties are associated with their high content of monounsaturated fatty acids, with oleic acid being the most abundant, in addition to other minor compounds, such as tocopherols, polyphenols, triterpenes and squalene [28].

Uvaol (urs-12-ene-3,28-diol) is a natural alcohol pentacyclic triterpene whose formula and molecular weight is C30H50O2 and 442.73 g/mol, respectively. It has a structural isomer, erythrodiol, from which it only differs in the position of a methyl group, since it is located in carbon 19 while uvaol presents it in carbon 20. The most notable feature of this compound is that it exhibits two hydroxyl groups in remote positions, specifically in carbons 3 and 28 (Figure 1A) [29]. Among the described set of triterpenes present in olive oil, uvaol has the lowest characterization of its bioactive properties [30]. Martin et al. [31] studied the effect of uvaol on the 1321N1 cell line and found that uvaol increased the rate of apoptotic cells, as well as producing an activation of the JNK. Allouche et al. [32] studied the effects of uvaol on MCF-7 cells observing a decrease in ROS production and cell viability.
Due to the promising results shown by the few studies carried out to date on the anticancer potential of uvaol, the aim of the present work was to evaluate its cytotoxic capacity, as well as its effect on proliferation, migration, morphology, cell cycle, apoptosis, stress oxidative, dual PI3K/MAPK signaling pathway and expression of protein markers involved in the processes described on the human liver cell line control WRL68 and the human cell hepatocarcinoma line HepG2.

2. Results

2.1. Uvaol produces morphological changes in HepG2 cells

Uvaol effect on cell morphology was analyzed using the IC₅₀ concentration of each cell line for 24 h. The images taken at 10 and 40 magnifications of the four experimental conditions described are shown in Figure 1B. Referring to WRL68 line, we can observe that its growth on the support is homogeneous, with the cells being initially separated from each other and presenting a fusiform morphology at 10 magnifications. When the treatment described is applied, the cells undergo a structure change, since they become rounded and have cytoplasmic projections towards the environment, due to cell death induced by the administration of uvaol. In addition, this causes them to rise from the support on which they grow.

The morphology of HepG2 cells in a control situation is triangular and shows an islet-shaped growth, each of them being well delimited with respect to the rest of the surrounding islets. Also, its cytoplasm is much more irregular than the presented by WRL68 cells. After the compound’s administration, as in the previous case, its characteristic morphology is blurred, becoming slightly more rounded, with very sharp projections and a loss of adhesion to the support.
2.2. Uvaol has a selectivity cytotoxic effect on the HepG2 cell lines

Uvaol effect was evaluated by the MTT assay on the WRL68 and HepG2 cell lines. The viability results obtained were represented in percentage (%) with respect to the different concentrations of compound administered (in µg/mL) for each cell line at 24, 48 and 72 h of exposure, showed using a sigmoidal adjustment (Figure 2A and 2B). Similarly, the IC_{20}, IC_{50} and IC_{80} values were calculated in the three time lapses described (Figure 2C). Figure 2A show that, for the WRL68 line, uvaol reduced cell viability in a dose and time-dependent way, since the IC_{20}, IC_{50} and IC_{80} values decreased with this treatment in a progressive form for the three lapses studied.

In the HepG2 line there is also a progressive decrease in cell viability according to concentration and exposure time (Figure 2B). The IC_{50} value obtained was 54.3 µg/mL for WRL68 line and 25.2 µg/mL for HepG2 line (Figure 2C). Therefore, the concentration needed to inhibit cell proliferation in tumor cells was half that those needed for the same purpose on the control line. The rest of the tests were carried out using the mentioned concentrations during 24 h of treatment.

![Figure 2A](image)

**Figure 2.** Cytotoxicity curves of uvaol during 24, 48 and 72 h in WRL68 (A) and HepG2 cells (B). IC_{20}, IC_{50} and IC_{80} values for the WRL68 and HepG2 lines after 24, 48 and 72 h of incubation with uvaol (C). These values are mean ± SEM (n = 9).

2.3. Anti-migratory positive activity of uvaol in HepG2 cells

The wound closure trial aims to assess the ability of cancer cells to migrate *in vitro*. Figure 3 collects the several images taken in each experimental condition at 10 magnifications for 0, 6, 18, 30 and 42 h after the wound was made. In the WRL68 line (Figure 3A) a progressive wound closure is observed, occurring at 18 h, in the control situation, the junction of the separated areas. The complete closure occurred at 42 h. In the treated populations, the separation line created is maintained at all measurements. The appearance of non-adhered and rounded cells on the wound may be due to the effect of the treatment, since approximately half of the cells present are dead.

For the HepG2 line (Figure 3B), a similar situation was observed, since in the control populations the wound is closed at the end, but in a much more progressive way due to a lower multiplication rate of this line. In the treated populations, the wound remains until the end of the trial.
Figure 3. Wound healing progression in cells treated and no treated with uvaol at IC₅₀ concentration (0, 6, 18, 30 and 42 h) in WRL68 and HepG2 cells.

2.4. *Uvaol induces G₀/G₁ arrest in HepG2 cells*

In order to analyze the possible effect of uvaol in the cell cycle for each line studied, the proportion of cells that were in each phase of the cycle (G₀/G₁, S and G₂/M) were measured in control and uvaol conditions. Figure 4 shows the images of the cell cycle assay generated by the flow cytometer during its analysis for each experimental condition.

Uvaol produced a significant decrease in the percentage of cells in phase G₀/G₁ and phase S, while, on the contrary, induced an increase in the G₂/M phase for the WRL68 line (Figure 4A). In the case of the HepG2 cell line (Figure 4B), treatment with uvaol resulted in a significant increase in the percentage of cells (24%) that were in the G₀/G₁ phase, while causing the reduction of cells in the G₂/M phase (20%). No differences were found in the S phase. When statistically comparing the results obtained between both lines, significant differences are observed in the behavior shown in each phase of the cell cycle after treatment with uvaol.
Figure 4. Cell cycle analysis obtained according to the Muse™ cell cycle kit. Panel A correspond to WRL68 cells and panel B to HepG2 cells. The cells were treated with IC₅₀ of uvaol for 24 h. Top: histograms from a representative experiment show the effect of uvaol on cell cycle profile. Bottom: percentage of cells in each cellular cycle phase. Values are expressed as mean ± SEM (n = 12). Different letters indicate significant differences between treatments for each cell cycle phase and asterisk indicate significant differences between cell lines for each treatment and cell cycle phase (p < 0.05).

2.5. Apoptosis is enhanced in HepG2 cells by Uvaol

Apoptosis assay provides information about the type of cell death that occurs in each line and for each situation studied: negative control, positive control (treatment with staurosporine with a 1µg/mL concentration for 2 h) and treatment with uvaol. Figure 5 includes the images of each experimental condition generated by the flow cytometer during its analysis. The data obtained reflect the percentage of viable cells, those that suffer apoptosis and those presenting necrosis (Figure 5).

Figure 5A shows how both the addition of staurosporine (control +) and uvaol produced a significant decrease in the number of viable cells in WRL68 line, which was accompanied by an equally significant increase in the number of apoptotic and necrotic cells in each situation with respect to control. In HepG2 cells (Figure 5B), treatment with staurosporine did not lead to an increase in apoptotic cells, while uvaol did induce a significant reduction in the percentage of viable cells, therefore, increasing the proportion of apoptotic cells. In none of the situations studied, changes in the rate of necrotic cells were generated.

When statistically comparing the results in both cell lines, significant differences were found in the death rate generated by uvaol in each case. The percentage of cells in apoptosis is higher in the HepG2 line, while, on the contrary, a higher rate of necrosis occurred in the WRL68 line, although significantly lower than the number of cells in apoptosis. Therefore, uvaol exerts a pro-apoptotic effect on both lines.
Figure 5. Apoptosis analysis obtained according to the Muse™ apoptosis kit. Panel A correspond to WRL68 cells and panel B to HepG2 cells. Treatments included cells not treated (negative control) and cells incubated with staurosporine (1µg/mL, positive control) or IC₅₀ of uvaol for 24 h. Top: dot plots show a representative experiment of the different treatments. Bottom: percentage of lived, apoptotic and necrotic cells for each treatment. Values are expressed as mean ± SEM (n = 12). Different letters indicate significant differences among treatments for each cell group and asterisk indicate significant differences between cell lines for each treatment and cell group (p < 0.05).

2.6. Uvaol decreases ROS production in HepG2 cells

Intracellular ROS levels were measured by FACS under the four generic test conditions described above. Figure 6 includes the images of each experimental condition generated by the flow cytometer during its analysis. The results show the percentage of cells in each situation studied that express ROS (ROS+) and those that do not express them (ROS-).

Uvaol treatment maintained the ROS levels produced by the WRL68 cell line without significant differences with respect to the control situation (Figure 6A). The highest levels of ROS were produced in the control situation in HepG2 cell line (Figure 6B). When treated with uvaol, a significant decrease in the percentage of cells expressing this type of reactive species appeared. When statistically comparing the results in both cell lines, it was observed that there were no significant differences in ROS levels between the WRL68 and HepG2 lines after treatment. In control situation, significant differences were observed in ROS production levels, since HepG2 express higher levels of radicals.

2.7. Uvaol produces up and down-regulation of target proteins in HepG2 cells

The expression of p53, c-Myc, Bcl-2, SOD and HSP-60 proteins for the WRL68 and HepG2 cell lines, in control situation and after treatment with the corresponding IC₅₀ concentration of uvaol for 24 h, was measured through Western blot technique. The level of expression obtained in each case was normalized with respect to the expression of actin (constitutive protein) and subsequently referred to that obtained in the control situation for the WRL68 line (Figure 7).
Figure 6. ROS quantification was performed according to the Muse™ Oxidative stress kit. Panel A correspond to WRL68 cells and panel B to HepG2 cells. Treatments included cells not treated and cells incubated with IC₅₀ of uvaol for 24 h. Top: dot plots show a representative experiment of the different treatments. Bottom: percentage of ROS negative (ROS-) and ROS positive (ROS+) values observed for each treatment. Values are expressed as mean ± SEM (n = 12). Different letters indicate significant differences between ROS levels for each treatment and ROS levels (p < 0.05).

Figure 7. Western-blot analysis of p53, c-Myc, Bcl-2, SOD and HSP-60 protein levels in WRL68 and HepG2 cells, untreated (WC and HC) and exposed to IC₅₀ of uvaol for 24 h (WT and HT). The quantification of protein levels by densitometric analysis is shown in bar graphs. The results are the means ± SEM (n = 9) and are expressed as percentage of expression compared to actin. WRL68 values were used as 100% of expression and the rest of treatments were referred to this one. Different letters indicate significant differences between treatments for each cell line and asterisk indicate significant differences between cell lines for each treatment (p < 0.05).
The expression of p53 increased in WRL68 line after treatment with uvaol regarding control, but remained unchanged in HepG2 cells, a situation that is repeated for SOD. In both cases, the percentage of control expression and after treatment for the HepG2 line was higher with respect to expression after treatment in WRL68. In the case of c-Myc, an increase in its expression was observed in WRL68 with respect to the control, while it was maintained in HepG2. c-Myc levels in the control situation in HepG2 cells were higher than its expression after treatment in WRL68. The expression of HSP-60 increased in both lines when applying the treatment, being the percentage of expression after the addition of uvaol in WRL68 equal to the control situation in HepG2. Finally, the treatment did not produce changes in the expression of Bcl-2 in WRL68 cells, while their expression levels decreased in HepG2 cells.

2.8. Uvaol modulate dual PI3K/MAPK signaling pathway in HepG2 cells

To analyze the mechanism by which uvaol exerts its anticancer activity, we studied whether such effect is produced through the dual PI3K/MAPK signaling pathway. Results are showed in Figure 8. Uvaol treatment produced a 22% decrease in cells that only activated the AKT /PI3K pathway, whereas the percentage of cells in which ERK1/2/MAPK was only activated, besides being too low, was not altered in WRL68 cells. However, an increase of 25% was observed in cells that activated the dual pathway (MAPK and PI3K) (Figure 8A). When net balance of activated signaling pathways is considered, no modification of PI3K pathway was observed, but an activation of 25% took place in ERK1/2/MAPK signaling pathway.

Figure 8. AKT/PI3K and ERK1/2/MAPK dual pathway determination was performed according to the Muse™ PI3K/MAPK Dual Pathway activation kit. Panel A correspond to WRL68 cells and panel B to HepG2 cells. Treatments included cells not treated and cells incubated with IC₅₀ of uvaol for 24 h. Top: dot plots show a representative experiment of the different treatments. Bottom: percentage of non-activated cells and cells with PI3K, MAPK and Dual pathway activated for each treatment. Values are expressed as mean ± SEM (n = 12). Different letters indicate significant differences between treatments for each activated pathway and asterisk indicate significant differences between cell lines for each treatment and activated pathway (p < 0.05).
In HepG2 cells, uvaol effect on the percentage of cells that only activated AKT/PI3K induced a decrease of 25%. Similar to WRL68 cells, the percentage of cells that only activated ERK1/2/MAPK, besides being too low, was not altered in HepG2 cells. Regarding to activated dual pathway (MAPK and PI3K), uvaol only produced a 9% increase (Figure 8B). The net balance, in HepG2 cells, resulted in an inhibition of 16% in AKT/PI3K signaling pathway, whereas ERK1/2/MAPK signaling pathway was only increased in 9%.

3. Discussion

Mediterranean diet is mainly characterized by the regular intake of olive oil, which presents in its composition different molecules with beneficial properties for health. Among them, pentacyclic triterpenes, such as uvaol, have been shown to have an anti-parasitic, anti-oxidant, anti-inflammatory and hepatoprotective activity, especially highlighting their potential as anticancer molecules [18]. Due to the lack of effective treatments against cellular hepatocarcinoma in advanced stages [33], and no researches about effect of uvaol have been performed in these type of cancer, this study was aimed to the characterization of the anticancer activity of uvaol, in the human cell lines WRL68 (hepatic control) and HepG2 (cellular hepatocarcinoma). For this purpose, its effect on proliferation, migration, morphology, cell cycle, apoptosis, oxidative stress levels and protein markers of the processes described on the liver lines mentioned were determined.

The cytotoxicity assay is a useful test to preliminarily detect compounds that can affect the number of healthy cells in a total population. This trial showed that uvaol exerts an inhibition of cell proliferation in a dose and time dependent manner. Especially noteworthy is the result obtained for the 24 h IC₅₀ concentration in both cell lines, being 25.2 µg/mL and 54.3 µg/mL for the HepG2 and WRL68 lines, respectively. As it can be seen, the concentration required to inhibit 50% of proliferation in control cells was more than twice the one used to inhibit the proliferation of tumor cells at the same rate, indicating greater susceptibility and specificity to the compound by hepatocarcinoma cells. To our knowledge, studies of the uvaol in cancer cells are limited. In this sense, similar results were observed in the human mammary tumor line MCF-7 in which uvaol produced anti-proliferative effects in a dose and time-dependent manner with values IC₅₀11.06 µg/mL and 44.27 µg/mL [32]. Other triterpenes olive derived, such as maslinic acid, have been tested in HepG2 cells, in which the cytotoxic effect was lower than the observed in this study, with a IC₅₀ of 47 µg/mL at 72 h [34]. These values demonstrate a greater cytotoxic effect of uvaol than maslinic acid. Moreover, oleanolic-type saponins lowered the growth and proliferation of HepG2 in transplanted tumor in mice [35].

Triterpenes present in olive oil, such as ursolic acid or oleanolic acid have demonstrated anti-migratory and anti-angiogenic activities on several tumor lines [18]. To study if uvaol also had this effect, a wound healing assay was performed in HepG2 cell line, confirming that this compound has an anti-migratory effect. Moreover, this effect was corroborated by a simultaneous morphological characterization, since it was observed that, after the addition of the compound, cells presented alterations in their structure and adhesion ability. Uvaol induced these same changes on the human astrocytoma line 1321N1, making cells show a loss of adhesion [31]. Furthermore, the administration of oleanolic acid in HepG2 caused a cellular retraction and the appearance of cytoplasmic extensions characteristic of the apoptosis process [36].

Some natural triterpenes exert anti-proliferative effects due to their interference with the progression of the cell cycle or by the induction of cell death through apoptosis [30]. The arrest of the cycle in some of its phases constitutes a defense mechanism that allows damage repair in DNA, characteristic of tumoral cells [4]. Likewise, apoptosis is an essential process in organisms, since it allows the elimination of cells, in a controlled process, whose behavior or characteristics are away from homeostasis [5]. For this reason, flow cytometry studies were conducted to determine the process involved in the cytotoxic effect of uvaol on the cell lines under study. The results obtained showed that this triterpene was capable of inducing cell death through apoptosis with the corresponding concentration of IC₅₀ in both cell lines. Similar results were found in lymphoma cells (U937), in which 10 and 100 µM of uvaol induced apoptosis [32]. Notwithstanding, the same concentrations of uvaol did not show this effect in MDA-MB-231 (triple negative breast cancer) or in
MCF-7 cells [32]. Uvaol-induced cell cycle arrest occurred in the G$_0$/G$_1$ phase for HepG2 cells, while in WRL68 it was in the G$_2$/M phase. The use of uvaol on the MDA-MB-231 line did not produce changes in the progression of the cycle [29], while a concentration of 44.27 µg/mL of uvaol on the MCF-7 line and of 22.11 µg/mL of oleanolic acid on the HepG2 line resulted in an arrest in the same phase of the cycle [32, 36], results that match with those obtained. Therefore, the anti-proliferative effect of uvaol on HepG2 cells is due to, simultaneously, the induction of apoptosis and an arrest in the G$_0$/G$_1$ phase of the cell cycle.

In cancer process, ROS levels are usually increased due to the generation of a pro-oxidant environment maintained over time. This situation of oxidative stress, generally induced by an exacerbated production of free radicals or by an imbalance in endogenous cellular antioxidant systems, can lead to the production of DNA damage, an initial step in neoplastic development [21]. For this reason, controlling ROS levels inside a cancer cell could be a good strategy to mitigate the genetic material damage or even prevent them. Triterpenes are characterized by having an antioxidant activity [18], a quality manifested in the HepG2 results obtained in the present study. Similar results were obtained in MCF-7 and MDA-MB-231 lines for uvaol and erythrodiol [29, 32]. However, these compounds produced an increase in the intracellular levels of ROS in 1321N1 cells, which also resulted in the reduction of mitochondrial potential and in an induction of apoptosis via the JNK kinase pathway [31]. Therefore, the action of uvaol on the oxidative state of cells is specific to each tumor cell line. Nevertheless, during normal detoxification process of any foreign compound, such as uvaol inside the cell, ROS can be also produced [37]. An augmentation of ROS levels in response to uvaol treatment did not occur in WRL68 cells, probably due to the increase of SOD expression found in the present study.

p53 and c-Myc proteins are directly involved in the regulation of cell proliferation, as well as in the succession of the different phases of the cell cycle and in the apoptosis process [5, 7]. For this reason, the expression profile of the mentioned proteins was characterized in WRL68 and HepG2 cell lines. Contrary to expectations, p53 levels were higher in the HepG2 than in WRL68 cells. This may be due to the fact that, despite being described a decrease in p53 expression in patients with HCC due to mutations at different points of the gene that encodes it (TP53) [8], HepG2 line has this gene intact, being probably induced its expression by situations far from homeostasis in cancer cells, such as uvaol inside the cell, ROS can be also produced [37]. An augmentation of ROS levels in response to uvaol treatment did not occur in WRL68 cells, probably due to the increase of SOD expression found in the present study.

An augmentation of ROS levels in response to uvaol treatment did not occur in WRL68 cells, probably due to the increase of SOD expression found in the present study.
Heat shock proteins (HSP) form a family with a fundamental role in the correct folding and functionalization of proteins synthesized inside the cell. Clinical studies in patients with HCC show that the expression of HSP-60 is diminished in tumor cells with respect to healthy livers. This finding is related to a greater invasive ability of this neoplasm and a lower survival rate in patients. The lower differentiation gives these cells greater mobility, resulting in a high rate of invasion and subsequent metastasis [41]. Our results show that uvaol treatment induces an increase in the expression of HSP-60 in WRL68 control line, being this rise more acute for the HepG2 line. This effect of uvaol in HCC lines is a promising result, since it is related to the results obtained by Zhang et al. [41]. These authors observed that after inducing an overexpression of the gene that codes for the HSP-60 in HepG2 cells, these cells developed a phenotype with lower migratory capacity and greater cell differentiation, thus decreasing their metastatic ability [41]. Together with HSP-60 overexpression, wound healing results obtained in this study confirm the effect of uvaol as a potential anti-migratory compound.

The AKT/PI3K pathway is known as one of the most important signaling routes, which participates in cell growth, proliferation, cellular apoptosis and cytoskeletal rearrangement [42, 43]. AKT is the major downstream target of the AKT/PI3K pathway. Besides its interaction with Bcl-2 family effectors, the survival signal to cells is transferred by phospho-AKT [44]. Many studies have demonstrated that this pathway is activated in several types of cancer [45]. The results of the present study showed that uvaol significantly decreased AKT/PI3K pathway in HepG2 cells, whereas no changes were observed in WRL68 line. On the contrary, levels of ERK1/2/MAPK were increased in both lines, although this increment was significantly lower in hepatoma cells. This up-regulation on MAPK pathway was consequence of the down-regulation on PI3K, since PI3K and Ras pathways can intersect by cross-talk among their downstream effectors [46]. In other HCC studies (HepG2, Huh-7, Hep3B, and Sk-Hep-1 cell lines) using triterpenoids, such as ursolic acid or platycodin D, the results also showed an inhibition of AKT/PI3K signaling pathway [47-49]. These results support the hypothesis that apoptosis induced by uvaol is mediated by the modulation of the AKT/PI3K signaling pathway in HepG2 cells.

4. Materials and Methods

4.1. Cell cultures

The cell lines used were WRL68 (model liver cells) and HepG2 (hepatocellular carcinoma), provided by “Centro de Instrumentación científica” (CIC) of the University of Granada. The cells were grown in Dulbecco’s modified Eagle medium (DMEM) and minimum essential medium (MEM), respectively. In both cases, they were supplemented with 10% heat-inactivated foetal bovine serum (FBS) and 1% streptomycin/penicillin antibiotics. They were kept in a CO\textsubscript{2} incubator at 37°C, 95% relative humidity and 5% CO\textsubscript{2}. Cells were passaged at preconfluent densities by the use of a solution containing 0.05% trypsin and 0.5 mM EDTA. The cells were seeded in the culture dishes at the desired density.

4.2. Uvaol solution

The compound tested in the experiments performed was uvaol, provided by Sigma®, with a purity greater than 95%. A stock solution of uvaol with a concentration of 1mg/mL (in 40 \mu L of DMSO + 960 \mu L culture medium) was prepared and subsequently diluted in culture medium until reaching the concentrations required for each test.

4.3. Morphological changes

A morphological characterization of both cell lines in triplicate was carried out in a control situation (cells growing attached in culture medium) and after uvaol treatment corresponding to the
IC₅₀ calculated for 24 h. Optical microscopy images of the cultures were obtained in mentioned situations at 10 and 40 magnifications in each after 24 h of the treatment's application.

4.4. MTT assay

MTT assay was performed as described by Pérez-Jiménez et al. [50]. Briefly, samples containing 200 µL cell suspension (1·10⁴ cells/well) were cultured in 96-well plates, in triplicate of three populations of the both cell lines. Subsequent to adherence of the cells within 12 h of incubation, Uvaol was added to the wells at a concentration between 0–140 µg/mL and maintained during 24, 48 and 72 h. MTT was dissolved in the medium and added to the wells at a final concentration of 0.5 mg/mL. Following 2 h of incubation, the generated formazan was dissolved in DMSO. Absorbance was measured at 570 nm in a multiplate reader (Bio-tek®). The concentrations that caused 20, 50 and 80% of inhibition of cell viability (IC₂₀, IC₅₀ and IC₈₀) were calculated following the formula: % cell viability = (A₀ − AT)/ A₀·100, where A₀ is the control absorbance (100% of cell viability) and AT is the absorbance of the incubated cells with the different concentrations of uvaol. OriginPro 8 (OriginLab Corporation, USA) was used to perform a dose-response analysis by the following formula:

\[ y = A_1 + \frac{A_2 - A_1}{1 + 10^{(\log x_0-x)p}} \]

In which Logx₀ is the center of the curve, p the slope, A₁ the lower asymptote and A₂ the upper asymptote in the adjustment model described.

4.5. Scratch assay

The wound healing or scratch assay was used to assess the migration capacity of the WRL68 and HepG2 cell lines. With this objective, 3·10⁵ cells were seeded per well in a 6-well plate in triplicate for each cell line. When the populations reached a confluence of 80-90%, a sterile pipette tip was used to disrupt in a straight line (make a wound) the layer of cells attached to the culture surface. Subsequently, it was washed with PBS to prevent the cells that had been lifted from being able to rejoin. The control and monitoring of cell migration was carried out by imaging with optical microscopy the culture at different times (0, 6, 18, 30 and 42 h) at 10 magnifications from the realization of the wound to be able to identify the possible differences between the control cases (growing cells attached in culture medium) and after the addition of the IC₅₀ concentration for 24 h in both lines.

4.6. Cell sorting by flow cytometry

1.5·10⁵ cells were seeded per well in 24-well plates for each cell line (quadruplicates for three different populations of each cell line). After 24 h allowing the cells to adhere, they were separated into 4 different groups: negative control WRL68 and HepG2 populations and WRL68 and HepG2 populations treated with the concentration corresponding to their uvaol IC₅₀ for 24 h (in addition to other specific conditions of each test described in the corresponding section). Negative control populations were incubated only with the appropriate culture medium. The samples were analyzed in the Muse™ Cell Analyzer.

4.6.1. Cell cycle assay

The method is based on the analysis of the cell cycle through the discrimination of three populations: cells in phase G₀/G₁, S or G₂/M. For this, the Muse™ Cell Cycle Kit was used following the specification of manufacturer.

4.6.2. Apoptosis assay
Phosphatidylserine (PS) is a phospholipid that is usually found in the inner half of the cytoplasmic membrane, but is outsourced when loss of integrity occurs in the apoptosis process. The method is based on the recognition and binding to the PS exposed by annexin V protein, labeled with a fluorescent substance to detect the interaction and quantify it. We used the Muse™ Annexin V & Dead Cell kit, which provides the percentage of viable cells, apoptotic and affected by necrosis. A positive control was carried out, incubating cells with staurosporine (1µg/mL), a non-specific inhibitor of kinase proteins isolated from the Streptomyces staurosporeus species that shows the ability to induce the apoptotic pathway in a large number of tumor lines, being especially characterized this effect on the HepG2 cell line [35].

4.6.3. Measurement of ROS production

The method is based on the use of dihydroetide (DHE), a reagent capable of crossing the cell membrane and interacting with superoxide anions, a type of ROS. In this process, DHE oxidizes and forms the DNA intercalating agent ethidium bromide, detectable by its fluorescence emission. This allows two cell populations to be distinguished, those that express remarkable levels of ROS (ROS+) and those that do not (ROS-). The Muse™ Oxidative Stress kit was used for this purpose.

4.7. Protein extraction and Western Blot analysis

Triplicates of three different populations of each cell line, WRL68 and HepG2, were seeded in 6-well plates with a density of 2.5·10^5 cells per well. The corresponding IC50 concentration for 24 h was added in the treated populations. For protein extraction, each sample was resuspended in 20 µL of RIPA buffer (150 mM NaCl, 1% Igepal, 0.5% deoxycholic acid, 0.1% SDS, 50 mM Tris HCl pH 7.5, 0.2M PMSF, 700 mM OV and Thermo Scientific® PierceTM inhibitor cocktail), and held on ice for 15 min. They were centrifuged at 15,000 g for 10 min at 4°C, the supernatant was collected and stored at -80°C for further analysis. The quantification of the protein concentration was carried out through the Bradford method.

The methodology used to western blots analysis is described by Mokhtari et al. [19]. Briefly, the initial separation of the extracts was performed by a 12% polyacrylamide gel electrophoresis under denaturing conditions (SDS-PAGE). A standardized load of 30 µg of protein per well was used after denaturing the samples at 95 °C for 5 min and adding the loading buffer (0.25 mM Tris-HCl pH 6.8, 10% SDS, 1M DTT and glycerol). The proteins were transferred, by the semi-dry transfer method, (60 mA per gel, 1h) using the TransBlot Turbo system (BioRad®), to a PVDF membrane. The membranes were blocked with blocking buffer (TBS, 0.1% Tween-20 and 3% skimmed milk) for 1 h at room temperature, incubating with the specific primary antibodies against the proteins studied at 4 °C overnight. The primary antibodies (from Santa Cruz Biotechnology®) were diluted in blocking buffer. The membranes were washed with TBS-T (TBS, 0.1% Tween-20) for 5 min three times under stirring and incubated with the corresponding secondary antibody (from Sigma®) (Table 1) for 1 h at room temperature, repeating the previous washing process later. These secondary antibodies have the enzyme horseradish peroxidase (HRP) coupled, which allows chemiluminescence to be detected in the presence of the protein band due to its ability to oxidize the luminol solution (ECL-plus Western-blot detection system, GE Healthcare). The reaction produced was captured inside a ChemiDoc Imaging System (Bio-Rad®). The program used to analyse the images obtained was Image Lab Software (Bio-Rad®). The expression of each protein was normalized referring to actin levels and were represented based on the results obtained for the control situation (WRL68 line without treatment) as percentage of expression (%). The expression obtained in each protein was analysed through the mentioned program in triplicate.
Table 1. Description of the polyclonal antibodies (IgG) used in Western Blot technique.

| Protein | Primary Antibody                  | Secondary Antibody      |
|---------|-----------------------------------|-------------------------|
| p53     | Rabbit anti-p53 antibody (1:500)  | Anti-mouse IgG antibody (1:5.000) |
| SOD     | Rabbit anti-SOD antibody (1:250)  | Anti-rabbit IgG antibody (1:5.000) |
| c-Myc   | Goat anti-c-Myc antibody (1:500)  | Anti-goat IgG antibody (1:5.000) |
| HSP-60  | Mouse anti-HSP-60 antibody (1:250) | Anti-mouse IgG antibody (1:5.000) |
| Bcl-2   | Rabbit anti-Bcl-2 antibody (1:1.000) | Anti-rabbit IgG antibody (1:5.000) |
| Actin   | Mouse anti-actin antibody (1:1.000) | Anti-mouse IgG antibody (1:5.000) |

4.8. PI3K/MAPK Dual Pathway Activation Assay

The Muse® PI3K/MAPK Dual Pathway activation kit was employed to examine both the PI3K and MAPK signaling pathways simultaneously using the Muse Cell Analyzer (Merck-Millipore). The protocol followed was performed as the manufacturer instructions. The samples (quadruplicates for three different populations of each cell line) were analyzed in the Muse™ Cell Analyzer.

4.9. Statistical analysis

The results were expressed as mean ± standard error of the mean (SEM). Likewise, the study of the statistical difference between the data groups was carried out through the analysis of the two-way variance (two way-ANOVA). When interactions between the analyzed factors were present, the analysis of the variance of one way (one way-ANOVA) was used followed by the Tukey test. The differences were considered significant for p values <0.05. Statistical analyses were performed using the IBM SPSS Statistics (IBM®) software.

5. Conclusions

In conclusion, taken together, the results of this study suggest that uvaol exhibits a potential anti-proliferative effect, through G0/G1 cell cycle arrest, apoptosis, by inhibition of AKT/PI3K signaling pathway, and decreased ROS levels on HepG2 human hepatocarcinoma cell line.

Author Contributions: E.E.R-P., A.P-J. and J.P. have designed the research plan; G.C.B-P., A.P-J., I.G.-C., A.M.P-P., F.J.R.-Z., E.S., RC and E.E.R-P. have performed the different experiments; E.E.R-P., J.P., A.P-J. and J.A.L. have analyzed the data and G.C.B-P., A.P-J. and E.E.R-P. have written the manuscript. All authors have read and agreed to the published version of the manuscript.

Funding: This research was funded by a research project (UJA2014/07/13) from the Research Plan, Action 7 of University of Jaén, Spain and by funds of the consolidated Researches Group BIO-157 and BIO-341, from the General Secretariat of Universities, Research and Technology of the Ministry of Economy, Innovation, Science and Employment.

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, or in the decision to publish the results.
