We investigate the azimuthal angular correlation between the lepton transverse momentum $P_\perp$ and the impact parameter $b_\perp$ in non-central heavy-ion collisions, where the leptons are produced through two-photon scattering. Among the Fourier harmonic coefficients, a significant $v_4$ asymmetry is found for the typical kinematics at RHIC and LHC with a mild dependence on the $P_\perp$, whereas $v_2$ is power suppressed by the lepton mass over $P_\perp$. This unique prediction, if confirmed from the experiments, shall provide crucial information on the production mechanism for the dilepton in two-photon processes.

I. INTRODUCTION

The flow phenomenon of final state particles in heavy-ion collisions is one of the most important observations that signals the collective modes of the quark-gluon plasma created in these collisions [1–6]. They are defined as the anisotropy of final state hadrons in the transverse plane with respect to the impact parameter of the collision [7], e.g., in terms of $\cos(n\phi)$ where $\phi$ is the azimuthal angle between the hadron’s momentum $\vec{p}_h$ and the impact parameter $\vec{b}_\perp$. In this paper, we study the momentum anisotropy of the leptons from the pure electromagnetic process of $\gamma\gamma \rightarrow \ell^+\ell^-$ in heavy ion collisions. This anisotropy refers to the angular distribution of the leptons with respect to the reaction plane defined by the impact parameter of the collision. Although the associated phenomena may strongly resemble the conventional hadronic flow in experimental measurements, its underlying physics mechanism is from the initial state interactions. The comparison of the anisotropy between the leptons and hadrons will provide a unique perspective for the anisotropy phenomena in heavy-ion collisions.

Di-lepton production through the QED processes in heavy-ion collisions has a long history, mainly in the so-called Ultra-Peripheral Collisions (UPC) [8–18]. More recently, experiments at RHIC and LHC have pushed these measurements toward peripheral and central collisions. This was achieved by selecting the dilepton events through the kinematic constraints where the total transverse momentum of the dilepton is very small, well below the typical hadronic scale of 0.3 GeV. Significant deviations from the UPC case have been reported [19–23], where the mean value of the total transverse momentum of the lepton pair $q_\perp$ increases with centrality. Especially, from the ATLAS measurement, it reaches a value of about 100 MeV in the most central collisions at the LHC, whereas it is about 40 MeV for UPC case [24]. In this particular kinematic region, the lepton pairs are predominantly produced by the coherent electromagnetic fields of the incoming nuclei as initially demonstrated in Ref. [25]. These developments have generated quite an interest in the heavy-ion community. If it is confirmed that the observed effects indeed come from the medium interactions with the lepton pair, this shall lead to a potential probe to the electromagnetic property of the hot medium [19, 20, 24]. Therefore, the key step is to quantify the initial state contributions from the two-photon processes. To do that, we have to go beyond the previous calculations which only apply to the dilepton production in UPC events [24, 26–30].

On the other hand, this extension is not straightforward, since we have to compute the joint transverse momentum and impact parameter dependence for the incoming photon fluxes of the colliding nuclei [31, 32]. Different assumptions and models have been introduced [24, 26–32]. Among these calculations, the so-called QED calculation seems to suggest that the observed $P_T$–broadening effects may solely come from the initial state effects due to different geometry of the collisions [26]. However, the predicted azimuthal $\cos(2\phi)$ asymmetry between the total transverse momentum $q_\perp$ and the impact parameter $b_\perp$ remains to be confirmed in experiments [33]. This asymmetry depends on simultaneously determining the transverse momentum and impact parameter information and needs further studies.

The proposed anisotropy measurement in this paper is different from those in Refs. [26, 28, 29], where the azimuthal asymmetry depends on the total transverse momentum of the lepton pair $q_\perp$. In our study, the anisotropy is defined through the lepton momentum $P_\perp$ with respect to the impact parameter $b_\perp$. Therefore, we can integrate over $q_\perp$ to a certain value, e.g., 100 MeV, where the electromagnetic contribution dominates over the hadronic contributions as demonstrated in experiments at RHIC and LHC [19–23]. Because the total transverse momentum $q_\perp$ (order 100 MeV) is so small...
magnetic field $\vec{B}$ is perpendicular to the electric field in the transverse plane. Therefore, a physical gauge choice of the polarization vector $\vec{\epsilon} = \vec{b}_1$ with $b_1$ the unit vector of $\vec{b}_{1\perp}$ can be used to a quantum field theory calculation, especially when the polarization of the equivalent photon plays an important role.

The above physics is appropriately captured by introducing the photon distribution from the nucleus. Following the example of the generalized parton distribution (GPD) in nucleon [39], we introduce the generalized photon distribution. Similar to that of quark/gluon GPD [40], the photon GPD can be interpreted as the impact parameter dependent photon distribution. This is equivalent to the photon flux discussed in the literature. The photon GPD is defined through the following matrix,

$$x f^{\gamma\beta}_{\gamma^0}(x; \vec{b}_{1\perp}) = \int \frac{d^2k}{(2\pi)^2} e^{i\vec{k}\cdot \vec{b}_{1\perp}} \int \frac{d^2r}{(2\pi)^2} e^{i\vec{r}\cdot \tau_{1\perp}} \times \langle A, -\frac{\Delta}{2} | F^{j\alpha} \frac{r}{2} F^{j\beta} (-\frac{r}{2}) | A, \frac{\Delta}{2} \rangle,$$

where $F^{\mu\nu}$ represent the EM field strength. The photon GPD can be parameterized as

$$x f^{\alpha\beta}_{\gamma^0}(x; \vec{b}_{1\perp}) = \frac{\delta^{\alpha\beta}}{2} x f_\gamma(x; \vec{b}_{1\perp}) + \left( \frac{\vec{b}_{1\perp} \cdot \vec{b}_{1\perp}}{b_{1\perp}^2} - \frac{\delta^{\alpha\beta}}{2} \right) x h_\gamma(x; \vec{b}_{1\perp}).$$

Here, $f_\gamma(x, \vec{b}_{1\perp})$ is the normal polarization averaged impact parameter dependent photon distribution, and $h_\gamma(x, \vec{b}_{1\perp})$ is conventionally referred to as the helicity flip photon GPD, similar to the helicity flip gluon GPD [41–43]. When $x$ is sufficiently small ($x < \frac{1}{2m_p}$), photon distribution is dominated by these coherently generated due to the $Z^2$ enhancement where $Z$ is the nuclear charge number. By treating the external electromagnetic field of a relativistic nucleus as a classical Coulomb potential, the associated coherent photon distributions can be readily computed in terms of the nuclear charge form factor,

$$x h_\gamma(x, \vec{b}_{1\perp}) = x f_\gamma(x, \vec{b}_{1\perp})$$

$$= 4Z^2 \alpha x f_\gamma(x, \vec{b}_{1\perp})$$

$$= 4Z^2 \alpha \left| \int \frac{d^2q}{(2\pi)^2} e^{i\vec{q}\cdot \vec{b}_{1\perp}} \frac{\vec{q}_\perp}{q^2} F_A(q^2) \right|^2 ,$$

where $q^2 = q_\perp^2 + x^2 m_p^2$ and $F_A$ represents the EM form factor for the nucleus, and $m_p$ being proton mass. One finds that for a given $b_{1\perp}$, coherent photons are fully linearly polarized due to the fact that $h_\gamma = f_\gamma$ in the above equation, see also the discussions in Ref. [10]. This relation essentially is the consequence of the property of highly boosted Coulomb field: the direction of the electric field generated by a spherically symmetric charge source distribution is parallel to the impact parameter. The similar relation between unpolarized photon TMD and linearly polarized photon TMD was also established in Ref. [28]. In Ref. [44], the above photon flux $f_\gamma(x, \vec{b}_{1\perp})$
III. ANISOTROPY OF LEPTONS IN TWO-PHOTON PROCESSES

One naturally expects that the helicity flip photon GPD could introduce a cos 4\(\phi\) modulation in the azimuthal distribution of di-lepton produced in two-photon processes as the linearly polarized photon TMD does due to the similar photon polarization tensor structure. However, the cos 4\(\phi\) azimuthal asymmetries induced by the helicity flip photon GPD and the linearly polarized photon TMD are different types. The angle \(\phi\) here refers to the azimuthal angle between leading lepton transverse momentum and the impact parameter of heavy-ion collisions. On the other hand, the cos 4\(\phi\) azimuthal asymmetry investigated in the previous work [28, 29] describes the correlation between lepton transverse momentum and the total transverse momentum of lepton pair.

The dominant channel for di-lepton production in peripheral and ultraperipheral heavy-ion collisions are the Breit-Wheeler process \(\gamma(x_1 P) + \gamma(x_2 P) \rightarrow e^+e^- (l_1) + e^- (l_2)\) where leptons are produced nearly back-to-back in the transverse plane and the total transverse momentum \(q_{\perp}\) is small (order 100MeV). For convenience, we further define \(\vec{P}_{\perp} = (\vec{l}_{\perp 1} - \vec{l}_{\perp 2})/2\), where \(\vec{l}_{\perp 1}\) and \(\vec{l}_{\perp 2}\) are the transverse momenta for the final state two leptons. In the back-to-back configuration, \(P_{\perp}\) is approximately equal to the leading lepton’s transverse momentum.

The differential cross section for the lepton will be normally azimuthal angular symmetric. However, the helicity-flip photon will contribute to an azimuthal asymmetry. The reason is the following. As shown in the previous section, the photon polarizations are correlated to the individual impact parameters \(b_{\perp 1}\) and \(b_{\perp 2}\) of the nuclei. Here, \(\vec{b}_{\perp 1,2}\) represent the positions of two incoming nuclei with respect to the interaction point where the lepton pair is produced. The collision impact parameter \(b_{\perp}\), which is the distance between two colliding nuclei centers, can be written as \(\vec{b}_{\perp} = \vec{b}_{\perp 1} - \vec{b}_{\perp 2}\). For a particular centrality bin with the corresponding impact parameter \(b_{\perp}\), we integrate out \(b_{\perp 1}\) and \(b_{\perp 2}\) with this constraint. Following Ref. [28], the azimuthal angle dependence can be computed from the lowest order QED which gives the following amplitude square

\[
|M|^2 = 2e^4 \left[ \left( \frac{u}{t} + \frac{t}{u} \right) - 2\cos (2 (\phi_1 + \phi_2)) \right], \tag{4}
\]

with \(u\) and \(t\) being the usual Mandelstam variables, the azimuthal angles \(\phi_1\) and \(\phi_2\) being the angles of \(\vec{b}_{\perp 1}\) and \(\vec{b}_{\perp 2}\) with respect to \(\vec{P}_{\perp}\). To obtain the differential cross section depending on the collision impact parameter \(\vec{b}_{\perp}\), we integrate out \(\phi_1\) and \(\phi_2\) of the above equation with the constraint that \(\vec{b}_{\perp} = \vec{b}_{\perp 1} - \vec{b}_{\perp 2}\). After the integration, the \(\phi_1\) and \(\phi_2\) dependence in Eq. (4) will convert into a \(\phi\)-dependence where \(\phi\) is the azimuthal angle between \(\vec{b}_{\perp}\) and \(\vec{P}_{\perp}\). In particular, the first term leads to an isotropic distribution of \(\phi\), whereas the second term \(-2\cos (2 (\phi_1 + \phi_2))\) results into an anisotropy of \(\cos (4\phi)\). Therefore, in addition to the usual isotropic term in the cross section, there is a nonzero \(v_4\) in the leading contributions as follows

\[
\frac{d\sigma}{d^2P_{\perp}dy_1dy_2db^2b_{\perp}} = \frac{2\alpha_e^2}{Q^4} [A + C \cos (4\phi)], \tag{5}
\]

where \(y_1\) and \(y_2\) are leptons’ rapidities, respectively. \(Q^2 = x_1x_2s\) is the invariant mass square of the lepton pair, where the incoming photons longitudinal momentum fractions \(x_1 = \sqrt{P_{\perp}^2/s} (e^{y_1} + e^{-y_1})\) and \(x_2 = \sqrt{P_{\perp}^2/s} (e^{-y_1} + e^{y_2})\) are determined by the external kinematics. Here we have neglected the lepton mass dependence in \(x_{1,2}\) for the typical kinematics at RHIC and LHC. The coefficients \(A\) and \(C\) read

\[
A = Q^2 - 2P_{\perp}^2 \int d^2b_{\perp 1}d^2b_{\perp 2}\delta (2 (\vec{b}_{\perp 1} - \vec{b}_{\perp 2})) \times x_1f_y(x_1,b_{\perp 1}^2)x_2f_y(x_2,b_{\perp 2}^2) , \tag{6}
\]

\[
C = -2 \int d^2b_{\perp 1}d^2b_{\perp 2}\delta (2 (\vec{b}_{\perp 1} - \vec{b}_{\perp 2})) \times \left[ 2 (\vec{b}_{\perp 1} \cdot \vec{b}_{\perp 2}) - \vec{b}_{\perp 1} \cdot \vec{b}_{\perp 2} \right] \times x_1h_y(x_1,b_{\perp 1}^2)x_2h_y(x_2,b_{\perp 2}^2). \tag{7}
\]

The above expressions are very similar to those in Ref. [28]. We have also computed for the \(v_5\) anisotropy, and found that they are power suppressed by the lepton mass in terms of \(m_{\ell}/P_{\perp}\). This is because the \(\cos (2\phi)\) asymmetry requires helicity flip in the QED process of \(\gamma\gamma \rightarrow e^+ e^-\), which is suppressed by the lepton mass. The lepton mass is too small to have any observational effects for \(v_5\) for the typical kinematics at RHIC and LHC.

Note that there is no Sudakov effects in Eq. (5). This is because the Sudakov effects come from the incomplete cancellation between real and virtual contributions from higher-order QED corrections. Since in our current study, we integrate out small \(q_{\perp}\), the real and virtual divergences cancel out completely. As a consequence, the Sudakov factor is absent in the differential cross section of Eq. (5).

The nuclear charge form factor used in our numerical evaluation is taken from the STARlight MC generator [45],

\[
F_A(q^2) = \frac{4\pi\rho^2}{q^2A + a^2q^2 + 1} \times [\sin (qR_A) - qR_A \cos (qR_A)], \tag{8}
\]

where \(R_A = 1.1A^{1/3}\)fm, and \(a = 0.7\)fm. This parametrization numerically is very close to the Woods-
Saxon distribution. The numerical results for the computed azimuthal asymmetries in the different kinematical regions for different collisions species are presented in Figs. 2 and 3. Here the azimuthal asymmetries, i.e. the average value of $\cos(4\phi)$ are defined as,

$$
\langle \cos(4\phi) \rangle = \frac{\int dP_s \cos(4\phi) \ dP_s S}{\int dP_s S}.
$$

In Fig. 2, we show the asymmetries as the functions of the impact parameter $b_\perp$ in the heavy-ion collisions at RHIC and LHC, respectively. As one can see, the general trend is that the asymmetry increases with $b_\perp$ until it reaches a maximal value when $b_\perp$ is slightly larger than $2R_A$. The maximal value of the asymmetry $-2\langle \cos(4\phi) \rangle$ ranges from 26% to 34% depending on the center-of-mass energy, lepton transverse momenta regions, and collision species. After reaching its maximal value, the asymmetry slowly decreases with $b_\perp$, but remain sizable until the impact parameter is very large.

In Fig. 3, we plot the asymmetries as functions of the lepton’s transverse momentum $P_\perp$ for Au-Au and Pb-Pb collisions. The asymmetries do not change dramatically with $P_\perp$. This is very much different from hadron’s $v_4$ in non-central heavy-ion collisions, where the transverse momentum dependence is one of the characteristic features of the medium flow. Of course, in the current case, we can not go to very small transverse momentum for the leptons. This is because we need to keep back-to-back kinematics ($q_\perp$ is small) for the dilepton and large transverse momentum for the leptons to guarantee the dominance from the QED two-photon scattering and the factorization formalism in Eqs. (6,7).

The momentum anisotropy of leptons can be measured through the azimuthal angular correlations between the lepton and hadrons, similar to what has been done for the hadron flow. Of course, due to the fluctuations, the fourth order event plane may not be well aligned with the impact parameter $b_\perp$. This will introduce considerable uncertainties in measuring the $v_4$ for leptons in central collisions, while this issue becomes less severe for peripheral events. The measurements will provide important information on the production mechanism for the dilepton.

**IV. CONCLUSIONS**

In summary, we have studied the electromagnetic anisotropy of the leptons in heavy-ion collisions, where the leptons are produced in the pure QED process of $\gamma\gamma \to ℓ^+ℓ^-$. Our study shows that there is a significant size of $v_4$ anisotropy, whereas $v_2$ vanishes due to small lepton mass. These observables are defined as the azimuthal angular asymmetries of the lepton’s transverse momentum with respect to the impact parameter of non-central heavy-ion collisions. The asymmetries evaluated in various kinematic regions and for different collisions...
species are shown to be rather sizable. The experiment confirmation of \( v_2 \)-anisotropy in Figs. 2 and 3 will help to identify the production mechanism of the lepton pair at low total transverse momentum in heavy-ion collisions. Any deviation will indicate other production channels. Once this is established, we can utilize the lepton pair to probe the EM property of the quark-gluon plasma.

The EM anisotropy of the leptons can be measured through the azimuthal angular correlations between the leptons and hadrons. The comparison of the phenomena between the lepton and hadrons shall provide useful information on the underlying physics in heavy ion collisions. In particular, because the lepton anisotropy comes from the initial EM field of the colliding nuclei in noncentral collisions while the hadron flow comes from the collective modes in the quark-gluon plasma, a detailed study of both observables will lead to a deeper understanding of the interface of the initial geometry and later interactions of the medium.
