Status epilepticus (SE) is a single seizure or recurrent seizures lasting for more than 30 minutes, in which the consciousness is not regained. Refractory status epilepticus (RSE) is defined as status epilepticus that continues despite treatment with benzodiazepines and one antiepileptic drug [1].

The incidence of seizure activity in patients with epilepsy associated with anesthesia is 3.4% [2], but RSE is rarely reported during emergence of anesthesia. We describe a patient with epilepsy who developed RSE during and after emergence from anesthesia.

A 5-year-old, 22 kg, female patient was presented for ventilating tube insertion. She had a history of traumatic subarachnoid hemorrhage, diffuse brain injury and basal skull fracture 2 years ago. She was diagnosed with simple partial seizure 14 months ago and had been treated with valproic acid 240 mg/day. She did not show seizure activity for 1 year. Preoperative valproic acid concentration was 53.9 ug/ml and electroencephalogram (EEG) was normal. Other preoperative evaluations were within normal value, but she showed rhinorrhea.

On the day of surgery, she received valproic acid 10 mg/kg IV during nil per os (NPO). The patient was taken to the operation room. The heart rate, noninvasive blood pressure, oxygen saturation and BIS (A-2000, Aspect Medical Systems Inc, Natick, MA, USA) were continuously monitored. After preoxygenation, induction of anesthesia was performed using thiopental sodium 110 mg iv and rocuronium bromide 10 mg iv. After intubation, anesthesia was maintained with sevoflurane in an air-oxygen mixture (fraction inspired oxygen concentration = 0.5). Arterial oxygen saturation remained greater than 98% during the intraoperative course. No episodes of hypoxia occurred during the procedure.

As the patient began to emerge from anesthesia (BIS value was approximately 70), focal clonic movement of the right face and right arm was occurred. We suspected seizure and gave her midazolam 4 mg iv, but focal clonic movement did not stop. Therefore, we gave her phenytoin 20 mg/kg iv for 20 minutes and started desflurane inhalation (end-tidal concentration was 8%). Her seizure activity ceased and BIS was below 10. We discontinued desflurane and tried to emerge her from anesthesia. After 10 minutes, she started focal seizure again (BIS values was 65). We started phenobarbital infusion 20 mg/kg for 20 minutes.

Fig. 1. Electroencephalogram in the intensive care unit shows rhythmic or periodic spikes in the left occipital region. Arrows are spike.
Her seizure activity did not stop after phenobarbital infusion. We planned to move her to the intensive care unit.

In the intensive care unit, we checked for complete blood count, electrolyte, arterial blood gas, urine analysis, liver function test, EEG and serum valproic acid level. EEG showed rhythmic or periodic spikes in the left occipital region and was suggestive of SE (Fig. 1). Serum valproic acid level was 36.2 ug/ml. Other laboratory values were within normal limit. We infused valproic acid 10 mg/kg for 1 hour. Focal seizure was stopped and she regained consciousness. She was discharged 2 days after without any other complication.

General anesthesia may increase seizure activity, such as withholding antiepileptic drugs while maintaining NPO status prior to surgery, sleep deprivation, and use of proconvulsant medications. Sevoflurane anesthesia causes epileptiform EEG activity and produce clinical evidence of seizures in patients with or without a history of epilepsy. Hypercarbia and hypoventilation during emergence from anesthesia may increase seizure susceptibility and prolong seizure duration [3].

Lowered antiepileptic drug level is a common cause of status epilepticus. In this case, postoperative serum valproic acid concentration was lower than preoperative level, despite of preoperative iv administration. There are two possible causes of lowered valproic acid level. First, the patient missed one or two dose of antiepileptic drugs after admission without notifying the medical staff. Second, phenobarbital and phenytoin are potent hepatic enzyme inducers. They may increase valproic acid metabolism and decrease plasma concentration [4].

Treatment of RSE starts immediately with additional agents. Most often recommended drugs for use as a continuous infusion are midazolam, propofol, pentobarbital and thiopental. Continuous drug infusion in RSE is titrated to achieve an EEG burst suppression pattern. If continuous EEG monitoring is not available, BIS monitor can be used to guide titration of anesthetics in RSE [5].

In conclusion, we report a case of RSE during emergence of general anesthesia that may be caused by sevoflurane anesthesia and lowered antiepileptic drug concentration.
