Abstract
Odontomas are the most common type of odontogenic tumors. They are included under the benign calcified odontogenic tumors. Odontomas are basically classified into two types, complex and compound odontomes. Generally, Odontomes are asymptomatic. Occasionally, signs and symptoms relating to their presence do occur in form of impactions. The presence of odontomes in the anterior region more often leads to the impaction of the impaction of the permanent anterior teeth. We report a case of a 13 year old male, who came to the Department of Orthodontics and Dentofacial Orthopedics, Uttaranchal Dental and Medical Research Institute, Dehradun, Uttarakhand with left maxillary central incisor impaction due to the presence of an odontome in the left maxillary central incisor region. The surgical removal of the odontome was carried out. Combined approach with surgical exposure and the application of an orthodontic force brought the impacted left maxillary central incisor down to its proper position in the dental arch.

Keywords: Odontomes, Impaction, Maxillary Central Incisor Impaction.

Introduction
Odontomas are hamartomatous lesions rather than true neoplasms which are classified into compound and complex.¹³⁴ Compound odontomas are malformations in which all the tissues are in organized pattern giving resemblance to the tooth whereas the complex odontomes do not have an organized arrangement of the tissues. These are variable in size and shape; however, whether they are complex or composite type, they usually have broader and wider cross-section and their presence will be more likely to impede the eruption of the central incisors than a supernumerary tooth.

Impactions are quiet common in the routine dental practice but the impactions of central incisors are the least frequent impacted teeth with an incidence rate of 0.06-3%.³⁴ Early diagnosis is very important and interceptive orthodontic treatment could not only improve skeletal malrelationship and eliminate functional interferences, but also may correct disturbances during the eruption.⁸

The maxillary incisors are the most prominent teeth in an individual’s smile, they are also the teeth that are on maximum display during speech in most individuals and the normal eruption, position and morphology of these teeth are crucial to facial esthetics and phonetics.⁹ As missing upper incisors are regarded as unattractive this may have an effect on self-esteem and general social interaction, and it is important to detect and manage the impaction as early as possible.¹⁰

In this case report we discuss the surgical removal of the odontome, followed by the surgical exposure of the impacted central incisor and the orthodontic traction of the impacted central incisor teeth.

Case Report
A 13 year old male came to the Department of Orthodontics and Dentofacial Orthopedics, Uttaranchal Dental and Medical Research Institute, Dehradun, Uttarakhand with the chief complaint of spacing in the upper front region of the jaw. The patient’s medical and family history was insignificant. Extraoral examination revealed a mesocephalic and mesoprosopic face with an orthognathic profile and an obtuse nasolabial angle (Fig. 1).

Fig. 1: Pre- treatment Extraoral Photographs
Intraoral examination showed the spacing in the maxillary anterior region along with the clinical absence of a permanent maxillary left central incisor with no evidence of eruption (Fig. 2).

**Fig. 2:** Pre- treatment Intraoral Photographs

Radiographic examination (maxillary occlusal radiograph) revealed the presence of the impacted maxillary right central incisor and an odontome (Fig. 3).

**Fig. 3:** OPG and classification of the impacted incisor.

The OPG revealed an α- angle of 25° and the impacted central incisor lies in sector 2 (According to the Ericsson and Kurol Classification)(Fig. 3). Cephalometric analysis reveals a class II skeletal base with class II molar relation, retroclined upper incisors, proclined lower incisor and a horizontal growth pattern (Fig. 4)(Table-1).

Fig. 5: Surgical removal of odontome and surgical exposure of the impacted central incisor and placement of the attachment.

Fig. 6: Mechanics for the traction of impacted central incisor.

The bone and the connective tissue covering the tooth were removed, and the odontome was removed and sent for pathological examination. Crown was exposed for bonding the Beggs bracket with a ligature wire tied to it. The flap was closed after bonding the lingual button, and the ligature wire was brought out and passively tied to the archwire. After 2 weeks, orthodontic traction of the impacted incisor was started (Fig. 6). 10 months since the commencement of the orthodontic therapy the central incisor was successful; results were seen in the patient (Fig. 7 and 8).
Results
After 12 months of active treatment, impacted right central incisor was successfully brought into proper position and normal functional occlusion was established (Fig. 7-9). The repositioned incisor had slightly irregular gingival contour. The mid-treatment radiograph showed no root resorption or alveolar bone loss. Regarding esthetic factors, patient was satisfied with the results.
Multidisciplinary treatment plan was planned: surgical removal of supernumerary teeth followed by orthodontic correction of the unerupted permanent maxillary left central incisor.

**Treatment Objectives**
1. Create the space for impacted central incisor
2. Orthodontic traction of impacted tooth
3. Establish an acceptable functional occlusion.

**Treatment Options**
The following are three possible treatment options.
1. Creation of space for impacted tooth, surgical crown exposure and removal of odontoma, and orthodontic traction of the impacted central incisor
2. Extraction of the impacted central incisor and temporary restoration with removable prosthetic denture, followed by a permanent restoration with bridge or an implant when growth ceases
3. Extraction of the impacted central incisor and closure of the space, converting the lateral incisor into the central incisor with subsequent prosthetic restoration.

After a thorough discussion of the various treatment with the patient’s parents, we decided to approach the first treatment option with patient’s and his parent’s consent.

**Treatment Plan**
The treatment was planned in three steps.
1. Create the space for impacted left central incisor
2. Surgical exposure of impacted central incisor and removal of odontoma
3. Traction of maxillary right central incisor, with special attention to the gingival recession.

**Treatment Progress**
Banding and bonding of the maxillary arch was done with the 0.022 X0.028” MBT bracket system. The initial alignment was performed with a 0.016-inch Ni-Ti wire, followed by a 0.016-inch stainless steel wire. The maxillary teeth were consolidated in the right and left quadrant along with the use of a NiTi open coil spring to create space for the incisorsThe patient was referred to the oral surgeon for exposure of the impacted incisor. The surgeon followed the closed eruption technique and raised a wide mucoperiosteal flap (Fig. 5).

**Discussion**
Odontomes are relatively common odontogenic lesions which are generally asymptomatic and are diagnosed mostly in the second decade of life. The most common site for the presence of odontomes are in the anterior part of maxilla either between the roots the erupted teeth or ver the crown of the unerupted teeth leading to delayed eruption of the teeth or its impaction. An anomaly in the eruption of anterior teeth can affect facial esthetics and may cause psychological problems. Several techniques have been developed as a choice of treatment for this scenario. The successful management of the odontome and impacted central incisor is often a difficult task and enquires the joint expertise. It is important that orthodontist and oral surgeon together prepare a full proof treatment plan based on scientific rationale. Several reports have indicated an impacted tooth can be brought into proper alignment in the dental arch. The following factors are used to determine whether successful alignment of an impacted tooth can take place: (1) the position and direction of the impacted tooth, (2) the degree of root completion, (3) the degree of dilacerations, and (4) the presence of space for the impacted tooth. Orthodontic and surgical intervention should not be delayed to avoid unnecessary difficulties in aligning the tooth in the arch. Various surgical techniques have been described for exposing impacted teeth before orthodontic tooth movement. Two of the most commonly used surgical exposure techniques for labial impacted teeth are: the window approach and a technique which exposes only 4–5 mm of the most superficial portion of the labial aspect of the cusps while maintaining 2–3 mm of keratinized tissues. In this case, the available space for tooth alignment was sufficient and the tooth was in a favourable position. The tooth was brought into right anatomical position in the dental arch. If the impacted tooth is diagnosed with its root completely formed or if present in an unfavorable position, combination of surgical and orthodontic treatment has to be carried out.

**Conclusion**
The management of an odontome depends on its location, number and its relation to the adjacent tooth. The treatment of an unerupted maxillary central incisor tooth will depend on its state, position, and presence of enough space in the dental arch. If eruption is delayed, the permanent tooth should be exposed because it is important to allow the tooth to erupt into correct position as soon as possible. Impaction of maxillary permanent incisors is not a frequent case in dental practice, but its treatment is challenging because of the importance of these teeth in facial esthetics.
