Stochastic MPC with Multi-modal Predictions for Traffic Intersections

Siddharth H. Nair*, Vijay Govindarajan*, Theresa Lin, Chris Meissen, H. Eric Tseng, Francesco Borrelli

Abstract—We propose a Stochastic MPC (SMPC) formulation for autonomous driving at traffic intersections which incorporates multi-modal predictions of surrounding vehicles given by Gaussian Mixture Models (GMM) for collision avoidance constraints. Our main theoretical contribution is a SMPC formulation that optimizes over a novel feedback policy class designed to exploit additional structure in the GMM predictions, and that is amenable to convex programming. The use of feedback policies for prediction is motivated by the need for reduced conservatism in handling multi-modal predictions of the surrounding vehicles, especially prevalent in traffic intersection scenarios. We evaluate our algorithm along axes of mobility, comfort, conservatism and computational efficiency at a simulated intersection in CARLA. Our simulations use a kinematic bicycle model and multimodal predictions trained on a subset of the Lyft Level 5 prediction dataset. To demonstrate the impact of optimizing over feedback policies, we compare our algorithm with two SMPC baselines that handle multi-modal collision avoidance chance constraints by optimizing over open-loop sequences.

I. INTRODUCTION

Motivation

Autonomous vehicle technologies have seen a surge in popularity over the last decade, with the potential to improve flow of traffic, safety and fuel efficiency [1]. While existing technology is being gradually introduced into scenarios such as highway driving and low-speed parking, the traffic intersection scenario presents a complex challenge, especially in the absence of V2V communication. In any traffic scenario, an autonomous agent must plan to follow its desired route while accounting for surrounding agents to maintain safety. The difficulty arises from the variability in the possible behaviors of the surrounding agents [2], [3]. To address this difficulty, significant research has been devoted to modelling these agent predictions as multi-modal distributions [4], [5], [6]. Such models capture uncertainty in both high-level decisions (desired route) and low-level executions (agent position, heading, speed).

The focus of this work is to incorporate these multi-modal distributions for the surrounding agents (target vehicles) into a planning framework for the autonomous agent (ego vehicle). The main challenge in designing such a framework is to find a good balance between performance, safety, and computation time. We investigate this planning problem in the context of constrained optimal control and use Model Predictive Control (MPC), the state-of-the-art for real-time optimal control [7], [8]. We assume that predictions of the other agents are specified as Gaussian Mixture Models (GMMs) and propose a Stochastic Model Predictive Control (SMPC) framework that incorporates probabilistic collision avoidance and actuation constraints.

Related work

There is a large body of work focusing on the application of SMPC to autonomous driving [9], [10]. A typical SMPC algorithm involves solving a chance-constrained finite horizon optimal control problem in a receding horizon fashion [11]. The chance-constrained SMPC optimization problem, offers a less conservative modelling framework for handling constraints in uncertain environments compared to Robust MPC frameworks. In the context of autonomous driving, SMPC has been used for imposing chance constraints accounting for uncertainty in vehicles’ predictions in applications such as autonomous lane change [12], [13], cruise control [14] and platooning [15]. A common feature of works in these applications is that the predictions are either unimodal or the underlying mode of the multi-modal prediction can be inferred accurately.

In order to handle multi-modal predictions (specifically GMMs), the work in [16] and [17] proposes nonlinear SMPC algorithms that suitably reformulate the collision avoidance chance constraint for all possible modes and demonstrate their algorithms at traffic intersection scenarios. However, a non-convex optimization problem is formulated to find a single open-loop input sequence that satisfies the collision avoidance chance constraints for all modes and possible evolutions of the target vehicles over the prediction horizon given by the GMM. This approach can be conservative and a feasible solution to the optimization problem may not exist. To remedy this issue, we optimize over a class of feedback policies [18] which adds flexibility due to the ability to react to different realizations of the vehicles’ trajectory predictions along the prediction horizon.

The work in [19] and [20] is the closest to our approach. The former considers uni-modal predictions and fixes a policy (computed offline) for which the optimization problem can still be conservative. The latter proposes a Robust MPC scheme that optimizes over mode-dependent sequences for multi-modal distributions of the obstacle with bounded polytopic supports. However, the sequences are not a function of vehicles’ state trajectory predictions because this would require enumerating over all possible sequences of vertices of the support of the obstacle distribution, resulting in a formulation where the number of constraints is exponential in the prediction horizon.

Contributions

Our main contributions are summarised as follows:

- We propose a SMPC framework that optimizes over a novel class of feedback policies designed to exploit additional structure in the GMM predictions. These policies assume feedback over the ego vehicle state and the target vehicle positions, thus reducing conservatism. Moreover, we show that our SMPC optimization problem can be posed as a Second-Order Cone Program (SOCP).

- We present a systematic evaluation of our framework along axes of (i) mobility, (ii) comfort, (iii) conservatism, and (iv) computational efficiency at a simulated traffic intersection. To demonstrate the impact of optimizing over feedback policies, we include two baselines: (i) a chance-constrained Nonlinear MPC optimizing over open-loop sequences instead of feedback policies, we include two baselines: (i) a chance-constrained Nonlinear MPC optimizing over open-loop sequences instead of feedback policies, and (ii) an ablation of our SMPC formulation, which optimizes over open-loop sequences instead of feedback policies. In the interest of space, we defer proofs and extensive simulation results to our website.

II. PROBLEM FORMULATION

In this section we formally cast the problem of designing SMPC in the context of autonomous driving at intersections.

A. Preliminaries

Notation: The index set \( \{k_1, k_1 + 1, \ldots, k_2 \} \) is denoted by \( \mathbb{I}^{k_2}_{k_1} \). For any two positive semi-definite matrices \( M_1, M_2 \in \mathbb{S}^n_{+} \), we have \( M_1 \prec M_2 \iff M_2 - M_1 \in \mathbb{S}^n_{+} \). We denote \( \| \cdot \| \) by the Euclidean norm and \( \| x \|_M = \| \sqrt{M} x \| \) for some \( M \succ 0 \). Given random variables \( X \) and \( Y \), we write \( X \mid Y \) as a shorthand for \( X \mid Y = y \) (\( X \) conditioned on \( Y = y \)). Given a normal distribution \( N(\mu, \Sigma) \) and \( \beta \geq 0 \), define the \( \beta \)-confidence ellipsoid \( \mathcal{E}(\mu, \Sigma, \beta) = \{ x : \| x - \mu \|_{\Sigma^{-1}} \leq \beta \} \).

The binary operator \( \otimes \) denotes the Kronecker product. The partial derivative of function \( f(x, u) \) with respect to \( x \) at \( (x, u) = (x_0, u_0) \) is denoted by \( \partial_x f(x_0, u_0) \).

Intersection setup: Consider the intersection shown in Figure\(^1\) The Ego Vehicle (EV), depicted in green, is the vehicle to be controlled. All other vehicles at the intersection are called Target Vehicles (TVs).

EV modeling: Let \( x_t = [X_t, Y_t, \psi_t, v_t]^{\top} \) be the state of the EV at time \( t \) with \( [X_t, Y_t] \) and \( \psi_t \) being its position and heading respectively in global coordinates, and \( v_t \) being its speed. The discrete-time dynamics of the EV are given by the Euler discretization of the kinematic bicycle model [21], denoted as \( x_{t+1} = f^{EV}(x_t, u_t) \). The control inputs \( u_t = [a_t, \delta_t]^{\top} \) are the acceleration \( a_t \) and front steering angle \( \delta_t \).

The state and input constraints are given by polytopic sets \( \mathcal{X}, \mathcal{U} \) respectively.

As depicted by the green path in Figure\(^1\) we assume a kinematically feasible reference trajectory,

\[
\{(x_t^{ref}, u_t^{ref})\}_{t=0}^T
\]

is provided for the EV. This serves as the EV’s desired trajectory which can be computed offline (or online at low frequency) by solving a nonlinear trajectory optimization problem, while accounting for the EV’s route, actuation limits, and static environment constraints (like lane boundaries, traffic rules). However, this reference does not consider the dynamically evolving TVs for real-time obstacle avoidance.

TV predictions: We focus our presentation on a single TV although the proposed framework can be generalised for multiple TVs. Let \( o_t = [X_t, Y_t]^{\top} \) be the position (and state) of the TV at time \( t \). For the purpose of dynamic obstacle avoidance, we assume that we are provided predictions of the TV’s position for \( N \) time steps in the future, given by the random variables \( \{o_{t+k}\}_{k=1}^N \), where each random variable \( o_{t+k} \) is shorthand for \( o_{t+k}|o_t \), the position of the TV at time \( t+k \) conditioned on the current position \( o_t \). The predictions for the TV at time \( t \) is encoded as a Gaussian Mixture Model (GMM):

\[
\mathcal{G}_t = \{ p_{t,j}, \{N(\mu_{k[t,j]}, \Sigma_{k[t,j]})\}_{k=1}^N \}_{j=1}^J
\]

where

- \( J \) is the number of possible modes.
- \( P(\sigma_j = j|o_t) = p_{t,j} \in [0, 1] \) is the probability that the mode at time \( t \), denoted by \( \sigma_t \), is \( j \) for some \( j \in I^J \).
- \( o_{k[t,j]} \sim N(\mu_{k[t,j]}, \Sigma_{k[t,j]}) \), i.e., the position of the TV at time \( t+k \) conditioned on the current position \( o_t \) and mode \( \sigma_t = j \), denoted by \( o_{k[t,j]} \), is given by the Gaussian distribution \( N(\mu_{k[t,j]}, \Sigma_{k[t,j]}) \).

The multi-modal distribution of \( o_{k|t} \) is thus given by

\[
o_{k|t} \sim \sum_{j=1}^J p_{t,j} N(\mu_{k[t,j]}, \Sigma_{k[t,j]}) \quad \forall k \in \mathbb{I}^N_t.
\]

B. Qualitative Control Objectives

- Design a feedback control \( u_t = \pi_t(x_t, o_t) \) for the EV to track the reference trajectory\(^1\) while avoiding collisions with the TV, whose predictions are given by the GMM\(^2\).

- The algorithm to compute \( u_t \) must be computationally tractable and not overly conservative.

\(^1\)Supplementary material, videos, code @ Project Website

Fig. 1: Depiction of an unsignalized intersection with green Ego Vehicle (EV) and orange Target Vehicle (TV). The EV arrives first and intends to turn left (green path). The EV is provided 3 possible predictions of TV behavior in decreasing order of probability (red: give EV right-of-way, orange: turn left and yellow: go straight).
C. Overview of Proposed Approach

We propose a novel SMPC formulation to compute the feedback control $u_t$. The optimization problem of our SMPC takes the form,

$$\min_{\theta_t} J_{t}(x_t, u_t)$$

s.t.  
(4a)  
$$x_{k+1|t} = f^E_{k}(x_{k|t}, u_{k|t})$$

(4b)  
$$o_{k+1|t} = o_{t}^F$$

(4c)  
$$\mathbb{P}(g_k(o_{k+1|t}, x_{k+1|t}) \leq 0) \leq \epsilon,$$

(4d)  
$$x_{k+1|t} = x_{k+1|t} + \Delta x_{k+1} \in X \times \mathcal{U},$$

(4e)  
$$u_{t} \in \Pi_{0_{t}}(x_{t}, o_{t})$$

(4f)  
$$x_{0|t} = x_{t}, \quad o_{0|t} = o_{t},$$

(4g)  
$$\forall k \in \mathcal{I}_{N-1}$$

where $u_{t} = [u_{0|t}, \ldots, u_{N-1|t}]$, $x_{t} = [x_{0|t}, \ldots, x_{N|t}]$ and $o_{t} = [o_{0|t}, \ldots, o_{N|t}]$. The SMPC feedback control action is given by the optimal solution of (4) as

$$u_{t} = \pi_{\text{SMPC}}(x_{t}, o_{t}) = u_{t}^*$$

(5)

where the EV and TV state feedback enters as (4g).

The objective (4a) penalizes deviation of the EV trajectory from the reference (1) and the collision avoidance constraints with respect to polytopic state and input constraints $X, \mathcal{U}$ for the EV. The TV predictions in (4c) are obtained from the GMM (2) and assuming additional dynamical structure (discussed in Sec. III-B). Using this, our SMPC optimizes over a novel parameterized policy class (4) that depends on predictions of the EV’s and TV’s states as opposed to optimization over open-loop sequences which can often be conservative. This is our main theoretical contribution. Moreover, we show that (4) can be posed as a convex optimization problem, making it computationally tractable and amenable to state-of-the-art solvers. This is achieved by (i) a convex parameterisation of policy class $\Pi_{0_{t}}(\cdot)$, (ii) using affine time varying models to generate EV and TV state predictions in (4b) and (4c), (iii) using a convex cost function for (4a), and (iv) constructing convex inner approximations of (4a).

III. STOCHASTIC MPC WITH MULTI-MODAL PREDICTIONS

In this section, we detail our SMPC formulation for the EV to track the reference (1) while incorporating multi-modal predictions from (2) of the TV for obstacle avoidance.

A. EV prediction model

The EV prediction model (4b) is a time linear-varying model, obtained by linearizing $f^E_{k}(-)$ about the reference trajectory (1). Defining $x_{k|t} - x_{t}^{ref} = \Delta x_{k|t}$ and $u_{k|t} - u_{t}^{ref} = \Delta u_{k|t}$, we have $\forall k \in \mathcal{I}_{N-1}$,

$$\Delta x_{k+1|t} = A_{k|t} \Delta x_{k|t} + B_{k|t} \Delta u_{k|t} + w_{k|t}$$

$$A_{k|t} = \partial_x f^E_{k}(x_{k|t}^{ref}, u_{k|t}^{ref})$$

$$B_{k|t} = \partial_u f^E_{k}(x_{k|t}^{ref}, u_{k|t}^{ref})$$

(6)

where the additive process noise $w_{k|t} \sim \mathcal{N}(0, \Sigma_{w})$ (i.i.d with respect to $k$) models linearization error and other stochastic noise sources. Consequently, the polytopic state and input constraints (4e) are then written as chance constraints $\forall k \in \mathcal{I}_{N-1}$,

$$\mathbb{P}(\Delta x_{k+1|t} \in \Delta x_{k} \times \Delta u_{k}) \geq 1 - \epsilon$$

B. TV prediction model

Notice that the multi-modal distribution of the random variable $o_{k+1|t}$ is independent of the random variable $o_{k+1|t}$, i.e., $o_{k+1|t} | o_{k+1|t} \neq o_{k+1|t}$ if $o_{k+1|t} \neq o_{k+1|t}$. However, since the TV positions are governed by the laws of motion, it is reasonable to assume dynamical structure to link positions at consecutive time steps such that $o_{k+1|t} | o_{k+1|t} \neq o_{k+1|t}$. Thus, a measurement of $o_{k+1|t}$ reduces the uncertainty in $o_{k+1|t}$, which can be exploited by the policy class (4) to satisfy (4d). We construct a multi-modal distribution to model this assumed dynamical structure using the parameters of the GMM (2) as follows.

We model dynamical behavior by assuming $\forall k \in \mathcal{I}_{N-1}$, $\forall j \in \mathcal{I}_{j}$ if $o_{k+1|t} = O_{k+1|t}$, then $o_{k+1|t}$ is a standard deviation away from $o_{k+1|t}$. For safety, we would also like to ensure that the $eta$-confidence sets for the distribution of $o_{k+1|t}$ given by the original GMM (2) is contained within that of the new distribution.

Consider the following candidate for the conditional distribution $\forall k \in \mathcal{I}_{N-1}$, $\forall j \in \mathcal{I}_{j}$

$$o_{k+1|t} | o_{k+1|t} \sim \mathcal{N}(T_{k+1|t} o_{k+1|t} + c_{k+1|t}, \Sigma_{k+1|t})$$

where $\forall k \in \mathcal{I}_{N-1}$, $T_{k+1|t} = \sqrt{\Sigma_{k+1|t} \Sigma_{k+1|t}^{-1}}$,

$$c_{k+1|t} = \mu_{k+1|t} - \Sigma_{k+1|t}^{-1} \Sigma_{k+1|t}^{-1} \Sigma_{k+1|t}^{-1}$$

where $\Sigma_{k+1|t} = \sum_{n=1}^{N} \Sigma_{k+1|t}^{-1} \Sigma_{k+1|t}^{-1} \Sigma_{k+1|t}^{-1} \Sigma_{k+1|t}^{-1}$. So the $\beta$-confidence ellipsoid of the new distribution contains that of the distribution given by the GMM in (3), i.e.,

$$E(\mu_{k+1|t}, \Sigma_{k+1|t} + \Sigma_{k+1|t}, \beta) \subset E(\mu_{k+1|t}, \Sigma_{k+1|t}, \beta).$$

Proof: Appendix B in full version [22].

Model (3) describes inference over the state of the TV by conditioning the observations of the TV states on a given mode $\sigma_t = j$. To complete the description of the TV’s multi-modal predictions, we now discuss inference over the mode $\sigma_t$ using observations $o_{k|t}$. There are sophisticated methods for computing the posterior distribution $\mathbb{P}(\sigma_t = j | o_{k|t})$ (e.g. using Bayes’ rule or E-M) but these would complicate our SMPC model [4]. Instead, we assume $p_{\sigma_t|o_{k|t}} = p_{\sigma_t|o_{k|t}}(\sigma_t < k, \forall k \in \mathcal{I}_{N})$. At some $k$, the mode can be exactly inferred from the TV’s state. Motivated by [20], our model for determining $k$ is given by

$$\min \{k \in \mathcal{I}_{N}: E(\mu_{k+1|t}, \Sigma_{k+1|t}, \beta) \cap E(\mu_{k+1|t}, \Sigma_{k+1|t}, \beta) = \emptyset, \forall l \geq k, \forall j, j_2 \in \mathcal{I}_{j} \}$$

(9)
Thus $\bar{k}$ is the minimum time step along the prediction horizon such that all $\beta$-confidence ellipsoids for subsequent time steps are pairwise disjoint for all modes. Given $\bar{k}$, we assume that the mode of the $i$th TV can be determined using state $\sigma_k$ as given by

$$p_{k|t,j} = \begin{cases} 1 & \text{if } \sigma_k \in E(\mu_{k,t,j}, \Sigma_{k|t,j}, \beta) \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

and $p_{k|t,j} = p_{k|t,j} \forall k \in \mathbb{I}^{N-1}$. In summary, we use (8) and (10) to obtain the TV prediction model $f_{k|t}^{TV}(\cdot)$ in (4c) as the multi-modal distribution of $o_{k+1|t}$ conditioned on $o_k$,

$$o_{k+1|t} | o_k \sim \sum_{j=1}^{k} p_{k|t,j} \mathcal{N}(T_{k|t,j} o_k + c_{k|t,j}, \Sigma_{k+1|t,j}) \quad (11)$$

Defining $n_{k|t,j} \sim \mathcal{N}(0, \Sigma_{k+1|t,j}) \forall k \in \mathbb{I}_0^{N-1}, \forall j \in \mathbb{I}_1$, we can use properties of Gaussian random variables (closure under linear combinations and the orthogonality principle) to rewrite (11) as

$$o_{k+1|t} = T_{k|t,j} o_k + c_{k|t,j} + n_{k|t,j} \forall k \in \mathbb{I}_0^{N-1} \quad (12)$$

where the posterior distributions of the mode $\sigma$ are determined using

$$\sigma_k | o_k \sim \begin{cases} \sigma_t & \text{if } k < \bar{k} \\ \sigma_k | o_k \text{ given by } (10) & \text{if } k \geq \bar{k} \end{cases} \quad (13)$$

### C. Multi-modal Collision Avoidance Constraints

We assume that we are given or can infer the TV rotation matrices for each mode along the prediction horizon as $\{P_{k|t,j}\}_{j=1}^{k}$. For collision avoidance between the EV and the TV, we impose the following chance constraint

$$\mathbb{P}(g_k | P_{k|t,j}, o_k) \geq 1 \geq 1 - \epsilon \forall k \in \mathbb{I}_1^N \quad (14)$$

where $P_{k|t,j} = [\Delta X_k | \Delta Y_k | \vec{c}]^T$ with $P_{k|t} = [X_{ref,k} | Y_{ref,k}]^T$ given by (1), $[\Delta X_k | \Delta Y_k ]^T$ given by (6), and

$$g_k | P, o = \left\| \begin{bmatrix} \frac{1}{\alpha_a} & 0 \\ 0 & \frac{1}{\alpha_b} \end{bmatrix} R_k | o_k | (P - o) \right\|^2 \quad (15)$$

$a_{ca}$ is $a_{TV} + d_{EV}, b_{ca}$ is $b_{TV} + d_{EV}$ are semi-axes of the ellipsoid containing the TV’s extent with a buffer of $d_{EV}$. $g_k | P, o \geq 1$ implies that the EV’s extent (modelled as a disc of radius $d_{EV}$ and centre $P$) does not intersect the TV’s extent (modelled as an ellipse with semi-axes $a_{TV}$ and $b_{TV}$ and centre $o$, oriented as given by $R_k | o_k$). This constraint is non-convex because it involves the integral of the nonlinear function $g_k | \cdot$ over the joint distribution of $(P_{k|t,j}, o_k, \sigma)$. To address the multi-modality, we conservatively impose the chance constraint conditioned on every mode with the same risk level $1 - \epsilon$ because of the following implication

$$\mathbb{P}(g_k | P_{k|t,j}, o_k) \geq 1 \geq 1 - \epsilon \forall j \in \mathbb{I}_1^J$$

$$\Rightarrow \mathbb{P}(g_k | P_{k|t,j}, o_k) \geq 1 \geq 1 - \epsilon$$

where $g_k | j, P, o$ is defined by conditioning (15) on mode $j$.

To address the nonlinearity, we use the convexity of $g_k | j, (\cdot)$ to construct its linear under-approximation in the following proposition.

**Proposition 2:** For collision avoidance, define EV positions $\forall k \in \mathbb{I}_0^N, \forall j \in \mathbb{I}_1^J$ as $P_{k|t,j} = \mu_{k|t,j} + \sqrt{g_k | j, (\cdot)} (P_{k|t,j}^{ref} - \mu_{k|t,j})$. Then for the affine function, $g_k | j, P = \partial P g_k | j, P_{k|t,j}^{ref} (P - P_{k|t,j}^{ref}) + \partial o g_k | j, P_{k|t,j}^{ref} (o - \mu_{k|t,j})$, we have $\forall k \in \mathbb{I}_0^{N-1}$

$$\mathbb{P}(g_k | P_{k+1|t}, o_k) \geq 1 \geq 1 - \epsilon \forall j \in \mathbb{I}_1^J \quad (16)$$

**Proof:** Appendix C [in full version] [22].

We build on these approximations to complete the reformulation of (14) for EV and TV trajectories given by (6), (12) in closed-loop with a feedback policy.

### D. Predictions using EV and TV state feedback policies

![Fig. 2: In (a), solving (4) over-open-loop sequences $u_t \in \mathbb{R}^2 \times N$](image)

(a) Prediction with open-loop sequences $u_t \in \mathbb{R}^2 \times N$

(b) Predictions with policies $u_t \in \Pi_{\theta} (x_t, o_t)$

Given the EV model (6) and mode-dependent TV model (12), we propose the following feedback policy for the EV:

$$\Delta x_{k|t} = \sigma_k | (x_{k|t}, o_k) = \begin{cases} h_{k|t} + \sum_{l=0}^{k-1} M_{k|t} u_{k|t+l} + K_{k|t} o_{k|t}, & \text{if } k < \bar{k} \\ h_{k|t} + \sum_{l=0}^{k-1} M_{k|t} u_{k|t+l} + K_{k|t} o_{k|t}, & \text{if } k \geq \bar{k}, \sigma_t = 1 \\ \vdots & \vdots \\ h_{k|t} + \sum_{l=0}^{k-1} M_{k|t} u_{k|t+l} + K_{k|t} o_{k|t}, & \text{if } k \geq \bar{k}, \sigma_t = J \end{cases} \quad (17)$$

which uses State Feedback (SF) for the TV states but Affine Disturbance Feedback (ADF) for feedback over EV states instead of SF. As shown in [18], the ADF: $h_{k|t} + \sum_{l=0}^{k-1} M_{k|t} u_{k|t+l}$, is equivalent to SF: $h_{k|t} + F_{k|t} \Delta x_{k|t}$, but the state prediction $\Delta x_{k|t}$ with ADF is affine in $\Delta x_{k|t}$ and the policy parameters up to time $k$: $\{ h_{k|t}, \{ M_{k|t} \}_{l=0}^{k-1} \}_{t=0}^{k}$, whereas with SF, $\Delta x_{k|t}$ involves nonlinear products of the parameters, $F_{k|t}, \ldots, P_{k|t}$. This is beneficial because (7), (16) become affine chance constraints in the ADF policy parameters (at the cost of needing $O(N^2)$ parameters instead of $O(N)$ for SF). In the proof of Proposition 3 we show that despite using SF for the TV states, $\Delta x_{k|t}$ are affine in $\{ K_{k|t} \}_{k=0}^{\infty} \forall k \in \mathbb{I}_0^{N-1}$. This is beneficial for scaling our approach to multiple TVs because we use $O(2^N N^2 + 2N^{n_{TV}})$.
planning framework to address these predictions. Finally, we provide a set of metrics and baseline policies used to evaluate the performance of our approach.

A. CARLA Simulation Environment

The EV is tasked with passing through the intersection depicted in Figure 3 while avoiding any TVs simultaneously driving through the same intersection. The scenarios are:

1) EV turns left while TV drives straight.
2) EV turns right while TV turns left into the same road segment.
3) EV turns left while TV turns left into the opposite road segment.

To ensure improved repeatability of our experiments, we use the synchronous mode of CARLA. This ensures that all processing (prediction, planning, and control) is complete before advancing the simulation. Thus, our results only consider the impact of the control inputs selected and not the time delays incurred in computing them.

The control for the TV is described by a simple nonlinear MPC (NMPC) scheme to track a pre-specified reference. For realism, the TV’s NMPC also uses short predictions of the EV for simple distance-based obstacle avoidance constraints. Additionally, we note that while the intersection has traffic lights, these are ignored in our experiments. Effectively, each scenario is treated as an interaction at an unsignalized intersection.

B. Multimodal Prediction Architecture

A key assumption in our SMPC approach is that the TV’s future motion is described by a GMM (2). To generate this probability distribution, we implement a variant of the MultiPath prediction model proposed in [5]. The input to this neural network architecture is a semantic image and pose history for the target vehicle in the scene. These inputs are used to generate a GMM over future trajectories by regression with respect to a set of predetermined anchors and classification over the anchor probabilities. We note, however, that our SMPC approach is appropriate for any prediction model that produces a GMM trajectory distribution.

To train the model, we selected a subset of the Lyft Level 5 prediction dataset [24] with 16 anchor trajectories identified

Fig. 3: Routes used for EV and TV vehicles with the scenario indicated by the numeric label. The EV follows a green path, while the TV follows a red path with the same scenario index.

The next proposition characterises this optimization problem.

**Proposition 3:** The state predictions $\mathbf{x}_t$ in closed-loop with $\Pi_{\theta_t}(\mathbf{x}_t, \omega_t)$ are affine in $\{h_j^t, M_j^t, K_j^t\}_{j=1}^J$. If $\epsilon < \frac{1}{2}$, then the set of policy parameters $\Theta_t(x_t, \omega_t)$ is a Second-Order Cone (SOC).

**Proof:** Appendix D in full version [22].

E. SMPC Optimization Problem

We define the cost (4a) of the SMPC optimization problem (4) to penalise deviations of the EV state and input trajectories from the reference trajectory (1) as

$$J_t(x_t, u_t) = \mathbb{E} \left( \sum_{k=0}^{N-1} \Delta x_{k+1|t} Q \Delta x_{k+1|t} + \Delta w_{k|t} R \Delta u_{k|t} \right)$$

where $Q > 0, R > 0$. After explicitly substituting the dynamics constraints (6), (12), we obtain the EV control (5) from our SMPC formulation as:

$$\min_{\mathbf{h}_j^t, M_j^t, K_j^t} J_t(x_t, u_t).$$

The next proposition characterises this optimization problem.

**Proposition 4:** The SMPC control action (5) is given by solving the following Second-Order Cone Program (SOCP):

$$\min_{s. (h_j^t, K_j^t, M_j^t)} s$$

s.t.

$$\{h_j^t, K_j^t, M_j^t\}_{j=1}^J \in \Theta_t(x_t, \omega_t),$$

$$N_t(\{h_j^t, K_j^t, M_j^t\}_{j=1}^J) \leq s + \rho_t$$

where $N_t(\cdot)$ is convex and quadratic in $\{h_j^t, K_j^t, M_j^t\}_{j=1}^J$ and $\rho_t$ is a constant determined by $x_t$, the EV reference trajectory (1) and the process noise covariance $\Sigma_w$.

**Proof:** Appendix E in full version [22].

IV. EXPERIMENTAL DESIGN

In order to assess the benefits of our proposed stochastic MPC formulation, we use the CARLA [23] simulator to run closed-loop simulation. In this section, we describe the simulation environment, evaluated scenarios, and prediction framework used to generate multimodal predictions. We then show how the SMPC formulation is integrated into a
using k-means clustering. At runtime, we opted to truncate the GMM produced by MultiPath. In particular, we pick the top $J = 3$ modes and renormalize the mode probabilities correspondingly.

C. Motion Planning Architecture

Given the predicted multimodal distribution for the TV, we use the framework introduced in Section III to generate feedback control policies for deployment. In addition to predictions of the TV, a dynamically feasible EV reference trajectory (1) must be provided. In our work, a NMPC problem is solved using IPOPT [25] which tracks a high-level route provided by the CARLA waypoint API, while incorporating dynamic and actuation constraints. Given the EV reference (1) and TV predictions (2), the SMPC optimization problem (3) is solved using Gurobi [26] to compute feedback control (4). When an infeasible problem is encountered, a braking control is commanded. The corresponding control action $u_{t|t}$ is given as a reference to a low-level control module that sets the vehicle’s steering, throttle, and brake inputs. These loops are repeated until all vehicles in the scenario reach their destination.

D. Policies

We evaluate the following set of policies:

- **SMPC**: Our proposed framework, given by solving (17).
- **SMPC-OL**: This model is an ablation of our approach, where $u_t \in \mathbb{R}^{2 \times N}$ replaces (4) and the GMM (2) is used directly in (4c) instead of (11).
- **SMPC-BL**: Based off [17], a nonlinear SMPC algorithm is used with the collision avoidance chance constraints (4d) reformulated using VP concentration bounds. The optimization is performed over open-loop sequences, i.e., $u_t \in \mathbb{R}^{2 \times N}$ instead of (4d), and no additional structure is assumed as in (4c), i.e., $O_{k+1} \sim f_k^{TV}(\omega_t)$.

E. Evaluation Metrics

We introduce a set of closed-loop behavior metrics to evaluate the policies. A desirable planning framework enables high mobility without being over-conservative, allowing the timely completion of the driving task, while maintaining passenger comfort. The computation time should also not be exorbitant to allow for real-time processing of updated scene information. The following metrics are used to assess these factors:

- **Mobility**: (1) $\bar{T}_{episode}$: Time the EV takes to reach its goal normalised by the time taken by the reference.
- **Comfort**: (1) $\bar{A}_{lat}$: Peak lateral acceleration normalised by the peak lateral acceleration in reference, (2) $\bar{J}_{long}$: Average longitudinal jerk, and (3) $\bar{J}_{lat}$: Average lateral jerk. High values are undesirable, linked to sudden braking or steering.
- **Conservatism**: (1) $\bar{\Delta}\tau$: Deviation of the closed-loop trajectory from the reference trajectory, (2) $d_{min}$: Closest distance between the EV and TV, and (3) $\bar{F}$: Feasibility % of the SMPC optimization problem. While an increase in (1) and (2) corresponds to higher safety, a large value could indicate an over-conservative planner and result in low values of (3).
- **Computational Efficiency**: (1) $T_{solve}$: Average time taken by the solver; lower is better.

V. Results

Now, we present the results of the various SMPC policies (Section IV-D). For each scenario, we deploy each policy for 4 different initial conditions by varying: (1) initial distance from the intersection $\in \{10 \text{ m}, 20 \text{ m}\}$ and (2) initial speed $\in \{8 \text{ m}^{-1}, 10 \text{ m}^{-1}\}$. For all the policies, we use a prediction horizon of $N = 10$, a discretization time-step of $dt = 0.2$ s, and a risk level of $\epsilon = 0.05$ for the chance constraints.

The performance metrics, averaged across the initial conditions, are shown in Table I. In terms of mobility, SMPC is able to improve or maintain mobility compared to the baselines. There is a noticeable improvement in comfort and conservatism metrics, as the SMPC can stay close to the TV-free reference trajectory without incurring high acceleration/jerk and keeping a safe distance from the TV. Remarkably, SMPC was also able to find feasible solutions for the SMPC optimization problem 100% of the time in our experiments, because the formulation optimizes over policies. Finally, while the SMPC-OL ablation is the fastest in solve time (due to fewer decision variables), the SMPC can be used real-time at approximately 20 Hz with further optimization.

The results highlight the benefits of optimizing over parameterized policies in the SMPC formulation for the EV, towards collision avoidance given the multi-modal GMM predictions of the TV.

### Table I: Closed-loop performance comparison across all scenarios.

| Scenario | Policy      | Mobility $T_{episode}$ ($\bar{J}_{lat}$, $\bar{J}_{long}$, $\bar{J}_{lat}$) | Comfort $\bar{A}_{lat}$, $\bar{J}_{long}$, $\bar{J}_{lat}$ | Conservatism $\bar{\Delta}\tau$, $d_{min}$, $\bar{F}$ | Efficiency $T_{solve}$ (ms) |
|----------|-------------|-----------------------------------------------------------------|--------------------------------------------------------|-------------------------------------------------|---------------------------|
| 1        | SMPC-BL     | 1.603, 11.962, 93.07                                              | 1.620, 10.971                                         | 1.712, 12.334, 6.016                             | 5.396, 5.270, 98.66      |
|          | SMPC-OL     | 1.096, 2.072, 10.746                                             | 1.217, 6.554                                         | 1.370, 9.288, 78.01                              | 3.790, 4.848, 100.00    |

(24)

$$Q = I_{N+1} \otimes Q, R = 1_N \otimes R$$

(25)

B. Proof of proposition [7]

Defining $\eta_{k,t} \sim \mathcal{N}(0, \Sigma_{k+1,t}) \forall k \in \mathbb{Z}^{N-1}$, we can use the closure of Gaussian random variables under linear combinations and the orthogonality principle, to rewrite [3] as

$$o_{k+1,t} = T_{k,t}o_{k,t} - \mu_{k+1,t} + \epsilon_{k,t}$$

- Using the definition of $c_k(t,j)$, we have $o_{k+1,t} = T_{k,t}o_{k,t} - \mu_{k,t} + \epsilon_{k,t}$ and $\epsilon_{k+1,t} = \epsilon_{k,t}$. Thus,

$$E[|o_{k+1,t} - \mu_{k+1,t}|^2 | o_{k+1,t}] = E[|T_{k,t}o_{k,t} - \mu_{k,t} + \epsilon_{k,t}|^2 | o_{k+1,t}]$$
where the second to last equality comes from the definition of $T_{k[t,j]}$.

- Expressing $o_{k[t,j]}$ in terms of $o_t$, we get

$$o_{k[t,j]} = \prod_{l=0}^{k-1} T_{l[t,j]} o_0 + \sum_{m=0}^{k-2} \prod_{l=m}^{k-1} T_{l[t,j]} (c_{m[t,j]} + n_{m[t,j]})$$

Computing the mean and expectation of this random variable gives the desired distribution. Since the ellipsoids $E(k_{t,j}, \Sigma_{k[t,j]} + \Sigma + \Sigma_{k[t,j],\beta}), E(k_{t,j}, \Sigma_{k[t,j]})$ share the same center, the desired containment is verified by seeing that $\beta(\Sigma_{k[t,j]} + \Sigma + \Sigma_{k[t,j],\beta}) \succ \beta \Sigma_{k[t,j]}$.

### C. Proof of Proposition [2]

First note that $P_{k[t,j]}^{\sigma\alpha}$ is defined such that $g_{k[t,j]}(P_{k[t,j]}^{\sigma\alpha}, H_{k[t,j]}) = 1$. For any convex function $f(x)$, we have $\forall x_0, x : f(x) \geq f(x_0) + \partial f(x_0)(x - x_0)$. Since $g_{k[t,j]}(P, o)$ is convex, we have $g_{k[t,j]}(P, o) \geq g_{k[t,j]}(P^r_{k[t,j],H_{k[t,j]}}) + g_{k[t,j]}(P, o) = 1 + g_{k[t,j]}(P, o)$. So $g_{k[t,j]}(P, o) \geq 0 \Rightarrow g_{k[t,j]}(P, o) \geq 1$, and $\forall k, \forall k[t,j]$.

$$P(g_{k[t,j]}(P_{k[t,j], o_{k[t,j]}})) \geq 1 \Rightarrow 1 - \epsilon \forall j \in J^I_k$$

$$\Rightarrow P(g_{k[t,j]}(P_{k[t,j], o_{k[t,j]}})) \geq 1 \Rightarrow 1 - \epsilon \forall j \in J^I_k$$

### D. Proof of Proposition [3]

Let $\Delta x_t = [\Delta x_{t0}, \ldots, \Delta x_{tn_{t0}}^T]$, $\Delta u_t = [\Delta u_{t0}, \ldots, \Delta u_{tn_{t0}}^T]$, $\Delta e_t = [\Delta e_{t0}, \ldots, \Delta e_{tn_{t0}}^T]$, $o_t = [o_{t0}, o_{t1}, \ldots, o_{tn_{t0}}]^T$, and $n_t = [n_{t0}, n_{t1}, \ldots, n_{tn_{t0}}]^T$. Then the random variable $\Delta x_t$ for the EV trajectory with policy $\pi^T$ conditioned on the mode $\sigma_t = j$, given by $\Delta u_t = M^t_i W_i + h_i^t + K^t_i o_i^t$, can be written as

$$\Delta x_t = A_t \Delta x_{t0} + B_t h_i^t + B_t K^t_i (T_{t0} o_t + C^t_f + L_i n_t^t) + (E_t + B_t M_i^t) w_i.$$
