ABSTRACT

We use a sample of powerful \(z \approx 0.1\) type 2 quasars (‘obscured’; \(\log [L_{\text{AGN}}/\text{erg s}^{-1}] \gtrsim 45\)), which host kpc-scale ionized outflows and jets, to identify possible signatures of AGN feedback on the total molecular gas reservoirs of their host galaxies. Specifically, we present Atacama Pathfinder EXperiment (APEX) observations of the CO(2–1) transition for nine sources and the CO(6–5) for a subset of three. We find that the majority of our sample reside in starburst galaxies (average specific star formation rates – sSFR – of \(1.7 \text{ Gyr}^{-1}\)), with the seven CO-detected quasars also having large molecular gas reservoirs (average \(M_{\text{gas}} = 1.3 \times 10^{10} M_\odot\)), even though we had no pre-selection on the star formation or molecular gas properties. Despite the presence of quasars and outflows, we find that the expected AGN feedback ratios (\(M_{\text{gas}}/M_\bullet = 0.1–1.2\)) and depletion times (\(M_{\text{gas}}/\text{sSFR} = 0.16–0.95 \text{ Gyr}\)) are consistent with those expected for the overall galaxy population with matched stellar masses and sSFRs. Furthermore, for at least two of the three targets with the required measurements, the CO(6–5)/CO(2–1) emission-line ratios are consistent with star formation dominating the CO excitation over this range of transitions. The targets in our study represent a gas-rich phase of galaxy evolution with simultaneously high levels of star formation and nuclear activity; furthermore, the jets and outflows do not have an immediate appreciable impact on the global molecular gas reservoirs.

Key words: ISM: jets and outflows – ISM: molecules – galaxies: active – galaxies: evolution – galaxies: general – galaxies: ISM.

1 INTRODUCTION

The energy from accreting supermassive black holes (i.e. active galactic nuclei, AGN) is widely accepted to be responsible for the global quenching of star formation in massive galaxies (AGN feedback; e.g. see reviews in Alexander & Hickox 2012; Fabian 2012; Harrison 2017). However, the physical mechanisms by which this energy couples to the gas on galactic scales and its precise impact on the host galaxy remains unclear. Multiwavelength studies are proving to be vital in both determining the mechanism and impact of feedback (see e.g. Cicone et al. 2018; Cresci & Maiolino 2018).

AGN are thought to be able to remove gas from their host galaxies via outflows. These outflows can be powered by the interaction between interstellar gas and small-scale accretion disc winds (Faucher-Giguère & Quataert 2012; Zubovas & King 2012) or directly via radiation pressure on dust (Ishibashi & Fabian 2015; Thompson et al. 2015; Bieri et al. 2017; Costa et al. 2018a,b), particularly for AGN with high Eddington ratios (‘quasar’ or ‘radiative mode’). While typically thought to operate primarily by preventing hot halo gas from cooling, via the so-called ‘radio’ or ‘maintenance mode’ (e.g. Churazov et al. 2005), collimated jets are also likely to drive outflows of interstellar gas (Wagner, Bicknell & Umemura 2012; Mukherjee et al. 2016), blurring the division between ‘quasar’ and ‘maintenance’ modes (see e.g. Jarvis et al. 2019).

In particular, the potential impact of AGN is most commonly observed through high-velocity ionized gas outflows (see e.g. Karouzos, Woo & Bae 2016; Morganti 2017; Davies et al. 2020). However, if the direct impact of AGN upon star formation is to be understood, it is the cold (\(\sim 10\) K) molecular gas (primarily composed of \(\text{H}_2\)) that forms the fuel for star formation, which must be further used in the context of the current work.
considered ( Morganti 2017). Since cold molecular gas is not directly observable in H$_2$ emission, carbon monoxide ($^{12}$CO), which has a permanent dipole moment, is most often used as a tracer of these cold molecular clouds (see e.g. Bolatto, Wolfire & Leroy 2013; Carilli & Walter 2013, and references therein). Specifically, the ground-level transition ($J = 1 \rightarrow 0$) has an excitation temperature of just 5.53 K, making it a good tracer of the total cold molecular gas (see e.g. Bolatto et al. 2013), while higher-$J$ CO lines (i.e. $J \geq 4 \rightarrow 3$) are produced from warmer, denser gas (see e.g. van der Werf et al. 2010; Daddi et al. 2015; Mashian et al. 2015; Kamenetzky, Rangwala & Glenn 2017).

Molecular gas outflows traced by CO gas have been identified in both radio- and quasar-mode AGN (see e.g. Cicone et al. 2014; King & Pounds 2015; Morganti et al. 2015; Bischetti et al. 2019; Fotopoulou et al. 2019; Oosterloo et al. 2019; Lutz et al. 2020; Veilleux et al. 2020). However, these outflows typically only represent $\sim 10$ per cent of the molecular gas luminosity (see e.g. Fluetisch et al. 2019; Lutz et al. 2020) and so are difficult to observe. Instead, the impact of AGN on the molecular gas in their host galaxies is often probed through the total molecular gas content (see e.g. Bertram et al. 2007; Xia et al. 2012; Husemann et al. 2017; Rosario et al. 2018).

Specifically, the gas mass and the molecular gas fraction relative to the star formation rate (SFR) are used to assess the potential impact of the AGN on the star formation efficiency and/or their ability to deplete the molecular gas supply within the host galaxies (e.g. Kakkad et al. 2017; Perna et al. 2018). In addition to removing molecular gas through outflows, AGN and mechanical feedback from jets can heat the molecular gas, which both inhibits star formation and causes the CO to emit in higher transitions (see e.g. Papadopoulos et al. 2010).

Our recent results, combining integral field spectrographic (IFS) and radio observations, have identified a sample of luminous ($L_{\text{OIII}} > 10^{42}$ erg s$^{-1}$) type 2 (obscured) AGN with signatures of jets and extended ionized gas outflows. These systems represent the ideal environment to search for signatures of feedback since they have the strong potential to interact with their environments both mechanically and radiatively (Harrison et al. 2014, 2015; Lansbury et al. 2018; Jarvis et al. 2019). In this work, we use unresolved CO measurements of the (2–1) and (6–5) transitions, to investigate the molecular gas content of these systems and look for signatures of the impact of the AGN and jet in particular, through thermal excitation and depletion of the gas reservoir.

In Section 2, we introduce our sample, describe our spectral energy distribution (SED) fitting approach used to determine key galaxy and AGN properties (Section 2.1), and compare our sample to the star-forming main sequence (Section 2.2). Section 3 describes our data, data reduction (Section 3.1), and analysis (Section 3.2). In Section 4, we describe our results, and in Section 5, we compare the total molecular gas and CO excitation in our systems to literature results (Sections 5.1 and 5.2, respectively) and we discuss these results in the wider context of galaxy evolution in Section 5.3. We present our conclusions in Section 6. We adopt $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$ throughout, and assume a Chabrier (2003) initial mass function (IMF).

### 2 SAMPLE SELECTION AND PROPERTIES

Here we present observations of the molecular gas in nine type 2 quasars. This sample was designed to be representative of powerful local AGN, with signatures of feedback, and therefore is ideal for identifying the impact of the AGN on the molecular gas reservoir. In particular, by selecting sources with previously identified ionized gas outflows and radio jets, the AGN should be able to impact the molecular gas through radiative and/or mechanical feedback by exciting and/or removing the molecular gas.

In Fig. 1, we show how our targets were selected from the parent sample of 24 264 $z < 0.4$ spectroscopically identified AGN$^1$ presented in Mullaney et al. (2013). In Harrison et al. (2014), we selected 16 $z < 0.2$ type 2 AGN with luminous [O III] outflows: $L_{\text{OIII}} > 10^{41.7}$ erg s$^{-1}$ and full width at half-maximum (FWHM) $\geq 700$ km s$^{-1}$ (see Fig. 1). The only other selection criteria was an RA/Dec. cut to select sources observable from Gemini-South. Using IFS data, we revealed that these outflows are extended on $\gtrsim$ kpc scales. For this work, we selected the 9 of these 16 targets with the highest [O III] luminosities (i.e. $L_{\text{OIII}} > 10^{42}$ erg s$^{-1}$) and radio luminosities ($\log [L_{\text{1.4GHz}}/\text{W Hz}^{-1}] \geq 23.5$; see Fig. 1). In Jarvis et al. (2019), we established that the radio luminosity of these targets is dominated by emission from the AGN, with eight of the nine exhibiting extended radio structures on $\sim 1-25$ kpc scales, which are likely radio jets (J1010+0612 is the only target without any evidence for an extended radio structure). The spatial coincidence of these radio features to outflows and disturbed ionized gas features visible in the IFS data strongly suggests jet–gas interactions in the majority of this sample (see Harrison et al. 2015; Jarvis et al. 2019). The basic sample properties are provided in Table 1.

#### 2.1 SED fitting

A significant amount of the analysis in this paper relies on having reliable estimates of the SFRs and stellar masses in our systems without contamination from the AGN. Since the AGN in this work are all type 2, the AGN has only a small contribution to the ultraviolet (UV)–optical emission but may still contribute significantly to the infrared (IR) emission. As such, in Jarvis et al. (2019), we performed UV–IR SED fitting using the ‘Code Investigating GalAXy Emission’ (CIGALE)$^2$; Noll et al. 2009; Buat et al. 2015; Ciesla et al. 2015) to derive the host galaxy and AGN properties of this sample. We used data from GALEX, SDSS, 2MASS, WISE, IRAS, and, where available, archival, Herschel PACS and SPIRE, for these SED fits, corrected for Galactic extinction (see Jarvis et al. 2019). Specifically, CIGALE simultaneously fits the attenuated stellar emission, star formation heated dust emission, AGN emission (from the accretion disc and dust heating), and nebular emission. Of particular relevance for this work are the stellar mass ($M_*$) and the SFR of the host galaxies, which are listed in Table 1. We calculated these SFRs from the SED-derived IR luminosity due to star formation ($L_{\text{IR, SF}}$) and the relationship from Kennicutt & Evans (2012), converting from a Kroupa into a Chabrier IMF by multiplying by 0.94 (Madau & Dickinson 2014), specifically SFR $= L_{\text{IR}}/(2.57 \times 10^{45}) \times 0.94$, with $L_{\text{IR}}$ in erg s$^{-1}$ and SFR in M$_*$/yr$^{-1}$. For further details of the SED fitting, derived quantities, and uncertainties, we refer the reader to Jarvis et al. (2019).

In Table 1, the quoted uncertainties are 1$\sigma$ formal errors from the CIGALE fits and do not include systematics. However, there is a 0.3–dex systematic uncertainty expected on the IR luminosity and stellar mass from the SED fitting (Gruppioni et al. 2008; Mancini et al. 2011; Santini et al. 2015). This results in a 0.42–dex systematic uncertainty for the SFR values, from adding in quadrature the systematic uncertainties from the SED fitting and the 0.3–dex systematic uncertainty on the conversion between $L_{\text{IR}}$ and SFR (Kennicutt & Evans 2012). Our sources have stellar masses

---

$^1$Using a combination of ‘BPT’ diagnostics (Baldwin, Phillips & Terlevich 1981), and emission-line widths.

$^2$https://cigale.lam.fr.
in the range $8 \times 10^8 < M_* < 1.1 \times 10^{11}$ $M_\odot$ and SFRs in the range $8 < \text{SFR} < 84$ $M_\odot$ yr$^{-1}$. All but one of our sources (J1430+1339) are classified as luminous infrared galaxies (LIRGs) based upon their IR luminosities due to star formation in the range $10^{11}$–$10^{12}$ $L_\odot$; see Fig. 2.

We verified these values by performing independent SED fits using another code: AGNFITTER (Calistro Rivera et al. 2016). The main difference between this code and the CIGALE code is that CIGALE assumes an energy balance between the IR and optical emission for the host galaxy, where AGNFITTER considers the two almost at least equal to the energy attenuated from the stellar emission. For the three of our sources with Herschel observations, which have the
best available coverage of the FIR emission (namely J1100+0846, J1356+1026, and J1430+1339; see Jarvis et al. 2019), the IR-derived SFRs agree within 0.27 dex (i.e. within the systematic uncertainty). For the remaining six sources, the best SFR from AGNfitter is based on the optical emission alone and as such is a lower limit on the actual SFR (Calistro Rivera et al. 2016). In each case, this limit is consistent with our SFR from CIGALE. The stellar masses from AGNfitter are, on average, 0.19 dex higher than those from CIGALE (i.e. within the systematic uncertainty), and the only significant outliers are J1000+1242 and J1010+0612, which have AGNfitter-derived stellar masses 0.67 and 0.48 dex larger than those from CIGALE, respectively. We note that using the AGNfitter stellar masses and SFRs would not change the main conclusion of this work. In summary, we trust the CIGALE SED-derived stellar masses and SFRs used throughout this work, within the limitations of the unavoidable systematic uncertainties discussed above.

2.2 Our targets in the context of the star-forming main sequence

There is a long established trend observed between SFR and stellar mass for star-forming galaxies, which is commonly referred to as the ‘star-forming main sequence’ (see e.g. Brinchmann et al. 2004; Daddi et al. 2007; Elbaz et al. 2007; Noeske et al. 2007; Salim et al. 2007; Wyder et al. 2007). This relation provides a useful comparison to put our sample into the wider context of star-forming galaxies. Specifically, we consider where our galaxies lie in comparison to the redshift-dependent main sequence at its redshift and stellar mass (Sargent et al. 2014). Where the other main sequences checked were Bauermeister et al. (2019), the Max Planck Institute for Radio Astronomy’s P230, and the APEX-1 receiver (SHeFI 230-GHz band; Vassilev et al. 2018), the Max Planck Institute for Radio Astronomy’s PI230, namely the Swedish-ESO PI receiver for APEX (SEPIA180; Belitsky et al. 2018), in the available instrumentation over the period of observation, these observations due to the redshift range of the targets and changes in the atmospheric transmission. Due to observing constraints (e.g. the need for good weather for these observations; see Table 2), we only observed three of our targets in CO(6–5); however, these three are representative of the overall population (see Figs 1 and 2).

We observed CO(2–1) for our targets under proposal id. E-0100.B-0166 [PI: Jarvis] with the observations carried out between 2017 July 7 and 2018 December 29 with precipitable water vapours (PWVs) between 0.6 and 4.7 mm. Three different instruments were used for these observations due to the redshift range of the targets and changes in the available instrumentation over the period of observation, namely the Swedish-ESO PI receiver for APEX (SEPIA180; Belitsky et al. 2018), the Max Planck Institute for Radio Astronomy’s P230, and the APEX-1 receiver (SHeFI 230-GHz band; Vassilev et al. 2008). The instrument used for each source, the dates they were observed, and the PWV values during the observations are listed above.

3 OBSERVATIONS AND DATA REDUCTION

3.1 Data reduction

We use the Atacama Pathfinder EXperiment (APEX) to observe the spatially unresolved molecular gas emission in the CO(2–1) and CO(6–5) transitions. We observed CO(2–1) for the whole sample presented here and CO(6–5) for a representative subsample (J1010+0612, J1100+0846, and J1430+1339; see Figs 1 and 2). These specific transitions were selected based on a combination of scientific and observational constraints. Specifically, lower CO transitions (CO (1–0) in particular) are best used to trace the total cold molecular gas content (e.g. Bolatto et al. 2013; Carilli & Walter 2013) and the CO(2–1) transition is the lowest observable at the redshift of our targets with the available APEX instrumentation. Higher CO transitions trace molecular gas that has been excited by star formation, shocks and the AGN (e.g. Mashian et al. 2015; Carniani et al. 2019; Vallini et al. 2019). Specifically, the CO(6–5) transition was selected based on indications that it can be boosted by AGN activity and jets in particular (Papadopoulos et al. 2010), and because it was the highest transition that could be observed for our targets in a reasonable time using APEX, due to available instrumentation and the atmospheric transmission. Due to observing constraints (e.g. the need for good weather for these observations; see Table 2), we only observed three of our targets in CO(6–5); however, these three are representative of the overall population (see Figs 1 and 2).

We observed CO(2–1) for our targets under proposal id. E-0100.B-0166 [PI: Jarvis] with the observations carried out between 2017 July 7 and 2018 December 29 with precipitable water vapours (PWVs) between 0.6 and 4.7 mm. Three different instruments were used for these observations due to the redshift range of the targets and changes in the available instrumentation over the period of observation, namely the Swedish-ESO PI receiver for APEX (SEPIA180; Belitsky et al. 2018), the Max Planck Institute for Radio Astronomy’s P230, and the APEX-1 receiver (SHeFI 230-GHz band; Vassilev et al. 2008). The instrument used for each source, the dates they were observed, and the PWV values during the observations are listed above.
The beams of the APEX observations discussed here are ∼28 arcsec (∼52 kpc at a representative redshift of \(z = 0.1\)) for the CO(2–1) data and ∼9 arcsec (∼17 kpc at \(z = 0.1\)) for the CO(6–5) data. Based on the relatively large beams of the APEX data and considering the optical sizes of our targets, we do not expect any CO flux to fall beyond our observed beams, making beam corrections unnecessary.

### 3.2 Data analysis

We fit each averaged spectrum using Bayesian fitting and MCMC implemented through emcee (Foreman-Mackey et al. 2013). This Bayesian method is preferred over frequentist fitting techniques for this analysis since it is less sensitive to binning, provides realistic uncertainties, and for the upper limits in particular requires only minimal assumptions on the line profile (see Appendix A). We assume a single Gaussian profile for the line, and fit for the line flux \(N\), which we assume to be Gaussian. The results of the fitting are listed in Table 3 and shown in Figs 3 and 4.

### 3.3 Evaluating contamination from other sources and beam corrections

The beams of the APEX observations discussed here are ∼28 arcsec (∼52 kpc at a representative redshift of \(z = 0.1\)) for the CO(2–1) data and ∼9 arcsec (∼17 kpc at \(z = 0.1\)) for the CO(6–5) data. Based on the relatively large beams of the APEX data and considering the optical sizes of our targets, we do not expect any CO flux to fall beyond our observed beams, making beam corrections unnecessary.
Figure 3. Our APEX CO(2–1) data (black curve) for each source. Overplotted for each is the results of our Bayesian fitting to the emission line, specifically the Gaussian constructed from the 50th percentile value from the posteriors for each parameter (magenta; see Table 3). For the two non-detections, a black horizontal line at flux = 0 is plotted to help guide the eye.

Figure 4. Our APEX CO(6–5) data. All three are undetected. Grey vertical bands highlight frequencies where there are narrow atmospheric absorption features that can cause slightly higher noise. A black horizontal line at flux = 0 is plotted to help guide the eye.

However, the large CO(2–1) beam raises the possibility that other CO bright objects may be contaminating our flux measurements. To check for this scenario, we used higher spatial resolution ALMA CO observations. Specifically, we use the CO(1–0) and CO(3–2) images published in Sun et al. (2014) for J1356+1026, and for the other targets, we use preliminary CO(3–2) images from two proposals carried out by our group\(^7\) that have a spatial resolution of \(\sim 0.3–0.5\) arcsec and a maximum recoverable scale of \(\sim 4\) arcsec.\(^8\) The only target where a possible contaminating CO source was identified is J1010+0612 that has a CO(3–2) bright companion \(\sim 7\) arcsec away, which is within our CO(2–1) beam. Preliminary flux measurements from the ALMA data reveal that \(\sim 82\) per cent of the total flux is in our primary target of J1010+0612, a difference that is within the

\(^7\)Specifically, id. 2016.1.01535.S (PI: Lansbury), and id. 2018.1.01767.S (PI: Thomson).

\(^8\)For J1430+1339, the ALMA data have a maximum recoverable scale of \(\sim 19\) arcsec.
for each source. For the CO(2–1) data, all but J0958+1439 show distinct peaks in the posterior probability distributions of our nine targets in CO(2–1). None of the three sources observed in the CO(6–5) line (for all nine targets) in Fig. 3 and around the J1356 (median) of the posterior distribution for each parameter in Table 3, indicating a detection. Therefore, we detect seven of the seven detected sources (see Table 3). Our upper limit for J1356+1026 (i.e. \( L_{\text{CO}}^{(2-1)} < 6 \times 10^9 \) K km s\(^{-1}\) pc\(^2\)) is consistent with the observed value obtained by converting the total \( L_{\text{CO}}^{(1-0)} \) reported for this source in Sun et al. (2014) into CO(2–1) (i.e. \( L_{\text{CO}}^{(2-1)} = 0.82 \times 10^9 \) K km s\(^{-1}\) pc\(^2\)), where we have assumed \( L_{\text{CO}}^{(2-1)/(1-0)} \equiv r_{21} = 0.8 \) (see Section 5.1.2 for a discussion of the choice of \( r_{21} \)). J1356+1026 is discussed in more detail in Sections 5.1 and 5.3. We have no prior knowledge of the total CO emission for J0958+1439.

Overall, we detect the CO(2–1) line for seven of our nine targets with fluxes in the range 7–23 Jy km s\(^{-1}\). The two non-detected targets have upper limits of 21.5 and 33.1 Jy km s\(^{-1}\) (for J0958+1439 and J1356+1026, respectively). Our upper limits on the CO(6–5) fluxes are 110, 74, and 135 Jy km s\(^{-1}\) for J1010+0612, J1100+0846, and J1430+1339, respectively. For the CO(2–1) detections, we measured peak line velocities between \(-320 \) and \(50 \) km s\(^{-1}\) relative to the systematic redshifts in Table 1, and line widths (\( \sigma \)) between 150 and 200 km s\(^{-1}\); however, we defer a discussion of the molecular gas kinematics to future work.

We calculate the CO luminosities (following e.g. Solomon et al. 1997) for each source using \( L_{\text{CO}}^{(2-1)} (\text{K km s}^{-1}\text{pc}^2) = \frac{3.25 \times 10^7}{v_{\text{CO,rest}}} \left( \frac{D_L^2}{1 + z} \right) f \),

\(^{(2)}\text{where } D_L \text{ is the luminosity distance in Mpc, } v_{\text{CO,rest}} \text{ is the rest-frame frequency of the CO line in GHz (230.538 and 691.473 GHz for the CO(2–1) and CO(6–5) lines, respectively), and } f \text{ is the flux of the CO line in Jy km s}^{-1}. \text{This result in } L_{\text{CO}}^{(2-1)} (\text{2–1}) \text{values of } (1.4–7) \times 10^9 \text{ K km s}^{-1}\text{pc}^2 \text{for the seven detected sources (see Table 3). These are plotted as a function of IR luminosity in Fig. 5 and are discussed in the following section.}\)
5 DISCUSSION

In this work, we look for signatures of AGN feedback on the molecular gas in our quasar sample. They are luminous AGN with ionized outflows and jets that may be able to impact upon the gas supply either radiatively or mechanically (see e.g. Harrison 2017 for a review). We stress that although molecular outflows are commonly observed directly through broad, generally blueshifted emission-line components (see e.g. Fluetsch et al. 2019; Lutz et al. 2020); they are typically weak in CO emission (contributing ≤10 per cent of the total emission-line profile), which would be undetectable in our data. Here we focus on the galaxy-wide molecular gas content (Section 5.1) and CO excitation (Section 5.2) of our sample of extreme quasars and compare them to redshift-matched literature galaxy samples both with and without AGN.

5.1 Molecular gas content

In order to assess if our AGN have depleted their host galaxies’ gas reservoir or decreased their star formation efficiency, we compare our results to studies of general galaxy populations and other AGN samples. Specifically, we consider (1) their total CO luminosities (L _CO) compared to their IR luminosities (L _IR, corrected for the AGN contribution; Section 5.1.1); (2) how the molecular gas fractions (M _gas/M _) and depletion times (M _gas/SFR) compare to other samples when SFRs, stellar masses, and offsets from the star-forming main sequence (ΔMS) are taken into account (Section 5.1.2); and (3) the relationship between AGN properties and the molecular gas content and star formation of the host galaxy (Section 5.1.3).

5.1.1 L _CO–L _IR relations

The correlation of L _CO (which traces the molecular gas mass) and L _IR (which traces star formation) in star-forming galaxies is well studied (e.g. Kennicutt 1998; Genzel et al. 2010; Greve et al. 2014; Sargent et al. 2014). By directly comparing observable quantities, this analysis removes many of the assumptions that are needed to convert these values into physical parameters. A complication to this analysis, which is not always accounted for, is that AGN can contribute significantly to the IR emission (see e.g. Kereš et al. 2011). The careful SED fitting technique implemented in our work allows us to reliably consider only the IR luminosity from the star formation component, which is free from AGN contamination (i.e. L _IR, SF; see Section 2.1).

Numerous works have parametrized the L _CO–L _IR relation using different samples of galaxies and different CO transitions. Here we focus on the work of Sargent et al. (2014), which used CO observations of 130 z < 3 massive (M * > 10 ^10 M_sol) star-forming and starburst galaxies collected from a range of surveys. The size of the Sargent et al. (2014) sample and its coverage of similar galaxy properties as in this work make it an ideal comparison sample. They find a redshift-invariant log-linear relation between the L _CO and L _IR. We convert their relation from CO(1−0) into CO(2−1) using r _21 = 0.8 (Leroy et al. 2008; Sargent et al. 2014; Daddi et al. 2015; Tacconi et al. 2018). We compare the L _CO and L _IR values for the nine targets in our sample to this relation in Fig. 5.

The correlation of L _CO/L _IR is well parametrized by Sargent et al. (2014) for main-sequence star-forming galaxies (the main sequence and starburst relations for J0958+1439 and J1356+1026, respectively), but could also lie significantly lower. Specifically, we note that using the Sun et al. (2014) CO(1−0) luminosity for J1356+1026 would place it approximately four times lower than the Sargent et al. (2014) starburst relation (see Fig. 5). This source is discussed in more detail in Sections 5.1.2 and 5.3.

We find that two out of the seven CO(2−1) detected quasars are consistent with the L _CO–L _IR relationship for main-sequence star-forming galaxies, whilst the other five have L _CO values up to a factor of ~4 lower than the relation would predict for their L _IR (see Fig. 5). However, as highlighted by the colour scaling in Fig. 5, all of the targets with low L _CO compared to the Sargent et al. (2014) main-sequence relationship have high SFRs in relation to the main sequence (i.e. they have high ΔMS values; see Section 2.2). This is consistent with Sargent et al. (2014), who find that starbursts are offset to lower L _CO values by a factor of ~2.9, on average, compared to main-sequence galaxies (see dotted line in Fig. 5). Indeed, all of our quasars which fall below the L _CO–L _IR relationship for main sequence galaxies are classified as starbursts (i.e. ΔMS > 4) and fall within 0.3 dex of the Sargent et al. (2014) relationship for starburst galaxies. We note that similar results are found when comparing our sample to the LIRG and merger L _CO–L _IR relationships of Greve et al. (2014) and Genzel et al. (2010), respectively.

Based on our data, the two CO(2−1) non-detected targets could still be consistent with the expected relationships for star-forming galaxies (the main sequence and starburst relations for J0958+1439 and J1356+1026, respectively), but could also lie significantly lower. Specifically, we note that using the Sun et al. (2014) CO(1−0) luminosity for J1356+1026 would place it approximately four times lower than the Sargent et al. (2014) starburst relation (see Fig. 5). This source is discussed in more detail in Sections 5.1.2 and 5.3.

In summary, we find that at least seven of our nine targets have L _CO values consistent with those of the star-forming galaxy population at matched IR luminosities and at similar distance to the main sequence.

---

Figure 5. L _CO/(2−1) compared to the IR emission produced by dust-heated star formation between 8 and 1000 μm (L _IR, SF; see Section 2.1). Our sample are shown as circles, colour-coded by their distance from the main sequence (ΔMS; see Section 2.2). In the bottom right-hand corner is a representative error bar showing the systematic uncertainties (see Sections 2.1 and 4). The Sun et al. (2014) value for L _CO(1−0), converted to (2−1) using r _21 = 0.8, for J1356+1026 is shown as a black diamond. The black dashed and magenta dotted lines show the relationships from Sargent et al. (2014) for main sequence and starburst galaxies, respectively (see Section 5.1.1). Our quasars appear to follow the trend of star-forming galaxies, with those further from the main sequence agreeing more closely with starburst relation. J1010+0612 is highlighted with a red outline because the L _CO may be ≤18 percent overestimated (see Section 3.2).
From these analyses, there is no evidence that the observed ionized outflows and jets in our powerful quasars have had an instantaneous impact on the observed CO luminosities.

5.1.2 Molecular gas comparisons

The more physically motivated quantities to study are the gas fraction (ratio of the molecular gas mass to stellar mass) and the depletion time (ratio of the molecular gas mass to the SFR), which relates to how efficiently stars are being formed for a given molecular gas mass. Based on large galaxy samples, these molecular gas properties scale with redshift, stellar mass, and distance from the star-forming galaxy main sequence (see e.g. Tacconi et al. 2018; Liu et al. 2019, and references therein). In this work, we are not concerned with the physical significance of these relations, but use them as a tool to compare the molecular gas properties of our sample to the wider galaxy population.

We compare our data to the homogenized sample of Tacconi et al. (2018) limited to within $z \pm 0.05$ of the maximum and minimum redshift of our sample and only using their CO-based measurements. Specifically, the data compiled come from the xCOLD GASS (Saintonge et al. 2017), EGNOG (Bauermeister et al. 2013), and GOALS (Armus et al. 2009) surveys and from the sample presented in Combes et al. (2011). We identified AGN hosts for each sample using BPT-based AGN classifications (the same as used to identify our sample; see Section 2), where available, and including all AGN classes (e.g. low-ionization nuclear emission-line regions, Seyferts, quasars, composite; Baldwin et al. 1981). The galaxies in this redshift-matched comparison sample span the complete range of stellar mass, sSFR, and $\Delta M_5$ found for our sample (see Fig. 6).

To ensure consistency with the comparison sample, we calculate the molecular gas masses of our sample using the same procedure

11Combined CO(1–0) and (3–2).
as in Tacconi et al. (2018). Specifically, we follow the metallicity-dependent $\alpha_{CO}$ and mass–metallicity relation used by Tacconi et al. (2018) (see also Genzel et al. 2015) to calculate molecular gas masses following $M_{\text{gas}} = \alpha_{CO} \times L_{CO}(1-0)$. The resultant $\alpha_{CO}$ values for our sample range from 4.0 to 4.2. We convert from $L_{CO}(2-1)$ into $L_{CO}(1-0)$ using $r_{21} = 0.8$. The full details of the equations used and a table of derived values are presented in Appendix B. For our seven CO(2–1) detected targets, the derived molecular gas masses fall in the range of $9.9 < \log(M_{\text{gas}}/M_\odot) < 10.5$, with corresponding ranges of gas fractions and depletion times of $M_{\text{gas}}/M_\star = 0.1$–1.2 and $M_{\text{gas}}/\text{sSFR} = 0.16$–0.95 Gyr, respectively.

In Fig. 6, we compare our derived gas masses and depletion times to the Tacconi et al. (2018) population as a function of stellar mass, sSFR, and $\Delta_{\text{MS}}$. We note that the dependence on the choice of main-sequence relation adds additional uncertainty to $\Delta_{\text{MS}}$ compared to sSFR; however, $\Delta_{\text{MS}}$ has been shown to be more closely related to the molecular gas properties (see e.g. Tacconi et al. 2018; Liu et al. 2019) and we obtain consistent conclusions if we just consider sSFR. Within errors, our sources overlap with the comparison sample (non-AGN and AGN) in all of the common diagnostic planes shown in Fig. 6. To quantify this comparison, we perform a simple log-linear fit to the Tacconi et al. (2018) sample with AGN removed (see Fig. 6). Our sample have a median log-vertical offset of +0.1 in the gas fraction versus $\Delta_{\text{MS}}$ plane and +0.04 in the depletion time versus $\Delta_{\text{MS}}$ plane (ignoring the non-detections). This provides some evidence for moderately high ($\sim$0.1 dex) gas fractions in our sample, with respect to their position relative to the main sequence. However, we cannot rule out that the two non-detected sources in our sample could bring our average down. Specifically, calculating the gas mass for J1356+1026 using the total $L_{CO}(1-0)$ from Sun et al. (2014) would place it among the most gas-poor systems in the Tacconi et al. (2018) population, with a log-vertical distance from the Tacconi et al. (2018) line of $-0.61$ and $-0.66$ in gas fraction and depletion time, respectively (see Section 5.3).

The AGN included in Tacconi et al. (2018), which have no selection for high bolometric luminosity or outflows, go in the opposite direction to our CO-detected targets, with median log-vertical offsets of $-0.12$ in the gas fraction versus $\Delta_{\text{MS}}$ plane and $-0.07$ in the depletion time versus $\Delta_{\text{MS}}$ plane. We explore the possible role of AGN power further in Section 5.1.3.

It is important to consider possible systematic uncertainties in comparing AGN to non-AGN samples due to the assumptions required to calculate gas masses. For example, there is no consensus on if AGN have systematically different ratios of $L_{CO}(2-1)$ and $L_{CO}(1-0)$, which is used to convert between the two ($r_{21}$; see e.g. Ocaña Flaque et al. 2010; Papadopoulos et al. 2012; Xia et al. 2012; Husemann et al. 2017; Shangguan et al. 2020); however, we note that the observed range is modest ($0.4 < r_{21} < 1.2$) and we have adopted the mean value of 0.8 throughout this work (see e.g. Braine et al. 1993; Leroy et al. 2009). A larger uncertainty comes from $\alpha_{CO}$, which, for most galaxies, appears to have a value of $\sim$4, with slight dependences on metallicity and SFR (see e.g. Bolatto et al. 2013; Sandstrom et al. 2013, and references therein). However, $\alpha_{CO}$ may be significantly lower in LIRGs, submillimetre galaxies, mergers, starbursts, and AGN (as low as $\sim$0.6; see e.g. Bolatto et al. 2013; Sargent et al. 2014; Calistro Rivera et al. 2018). In our comparison to literature results, we have controlled for many of these differences, i.e. we are comparing like-for-like in sSFR and $\Delta_{\text{MS}}$ and made consistent assumptions (see Appendix B). However, we cannot rule out some level of systematic differences in $\alpha_{CO}$ for AGN, which could shift our sources to systematically lower gas masses than the non-AGN comparison sample. Finally, we note that a limitation of our comparison to the Tacconi et al. (2018) catalogue is that it does not provide information on detection fractions or report upper limits. However, if anything, this limitation will strengthen our suggestion that the majority of the quasars in our sample, are comparatively gas-rich.

To summarize, although we cannot control for unknown systematic variations in $\alpha_{CO}$, our quasar sample has molecular gas fractions and depletion times that are consistent with, or slightly higher than, the redshift matched comparison sample when considered in terms of their stellar masses, sSFRs, or distances to the main sequence. This implies no significant rapid depletion of the molecular gas supply despite the presence of kpc-ionized gas outflows and jets.

### 5.1.3 The impact of AGN on the molecular gas content

To investigate the relationship between AGN and the molecular gas content in more detail, we build upon the work of Saintonge et al. (2017), which found that the BPT selected AGN in the xCOLD GASS sample with the highest [O III]/H$\beta$ ratios (taken as a proxy of the power of the AGN radiation field) tend towards higher gas fractions. In Fig. 7, we plot gas fractions as a function of the [O III]/H$\beta$ ratio for both the xCOLD GASS sample and the quasars presented in this work. For a fair comparison with the Saintonge et al. (2017) data we, again, use $r_{21} = 0.8$, and follow their method to obtain $\alpha_{CO}$. That is, we use the metallicity- and $\Delta_{\text{MS}}$-dependent function of Accurso et al. (2017), which results in $\alpha_{CO}$ values between 3.3 and 6.0, and gas masses of $9.8 < \log(M_{\text{gas}}/M_\odot) < 10.5$ (for the seven detected targets; see Appendix B for full details).

Fig. 7 reveals that our sample, extending to the most extreme local AGN, with no pre-selection on molecular gas or star-forming properties, agrees with and strengthens the previous results from xCOLD GASS: The more extreme AGN (i.e. those with $\log([\text{O III}]/H\beta) \geq 0.6$) tend to have the highest gas fractions. On average, for the combined samples, we find $(M_{\text{gas}}/M_\star)_{\text{average}} = 0.02$ for the sources with $\log([\text{O III}]/H\beta) < 0.6$ and $(M_{\text{gas}}/M_\star)_{\text{average}} = 0.16$ for the sources with $\log([\text{O III}]/H\beta) > 0.6$ (excluding non-detections). We note that a similar trend is observed for our sample when the bolometric AGN luminosity from our SED fits (see Jarvis et al. 2019) is used instead of [O III]/H$\beta$.

As highlighted by the colour-coding in Fig. 7, the most extreme AGN with the highest gas fractions are hosted in galaxies with high levels of concurrent star formation. Specifically, we find increasingly high $\Delta_{\text{MS}}$ values for increasing [O III]/H$\beta$ values. Indeed, when considering instead of the gas fraction, the log-vertical offset of each AGN from linear fits to redshift and stellar mass matched Tacconi et al. (2018) samples in the gas fraction versus $\Delta_{\text{MS}}$ plane (see Section 5.1.2), the trend with [O III]/H$\beta$ disappears. Specifically, the median vertical offset of the combined sample with

---

12 Where the log-vertical offset for a point $(a,b)$ from a line $y = f(x)$ with both in log space, is defined as $b - f(a)$.

13 We also note that, although the Tacconi et al. (2018) work does not directly account for an AGN contribution to their stellar mass and SFR calculations, their sample does not include type 1 quasars and are typically low-power AGN (and therefore the AGN do not dominate the optical–UV part of the SEDs) so the impact is not expected to be strong.

14 We note that J0945+1738, J1000+1242, and J1356+1026 are strong starbursts and might be better described with a lower $\alpha_{CO}$ (see Appendix B); however, this would not change our conclusions.
sources in our sample. Specifically, we find triangles for upper limits; from the catalogues provided with Saintonge et al. parameters between the two samples. Sources with high \([\text{OIII}]/\text{H}^\beta\) matched in stellar mass and redshift to each population, to log(\([\text{OIII}]/\text{H}^\beta\)) to \(\text{H}^\beta\) exciting it. Through our APEX observations, we put constraints on 5.2 CO excitation and SFRs in Section 5.3.

The most ubiquitous source of CO excitation is photodissociation regions (PDRs) from the UV photons emitted from young stars. However, this mechanism is inefficient at exciting higher CO transitions. Shocks and/or X-ray emission (through X-ray-dominated region models, XDR), both of which can be powered by AGN or jets, are needed to further excite the CO gas (see e.g. Pereira-Santaella et al. 2013; Carniani et al. 2019).

\[
\log(\text{[OIII]}/\text{H}^\beta) < 0.6 \text{ is } -0.05, \text{ while the median value for the sources with } \log(\text{[OIII]}/\text{H}^\beta) > 0.6 \text{ is } \sim 0 \text{ (see also Section 5.1.2 and Fig. 6). We note, however, that our sample covers a very narrow range of } \text{[OIII]}/\text{H}^\beta \text{ and xCOLD GAS is not designed as an AGN survey and so, due to volume and redshift limits, does not contain any powerful AGN. Larger samples, uniformly covering AGN with a range of powers, would be needed to strengthen this observation. We discuss the impact of these results on the relationships between AGN activity, molecular gas masses, and SFRs in Section 5.3.}
\]

\[
\log([\text{OIII}]/\text{H}^\beta) < 0.6 \text{ is } -0.05, \text{ while the median value for the sources with } \log([\text{OIII}]/\text{H}^\beta) > 0.6 \text{ is } \sim 0 \text{ (see also Section 5.1.2 and Fig. 6). We note, however, that our sample covers a very narrow range of } \text{[OIII]}/\text{H}^\beta \text{ and xCOLD GAS is not designed as an AGN survey and so, due to volume and redshift limits, does not contain any powerful AGN. Larger samples, uniformly covering AGN with a range of powers, would be needed to strengthen this observation. We discuss the impact of these results on the relationships between AGN activity, molecular gas masses, and SFRs in Section 5.3.}
\]

\[
\text{The CO spectral line energy distribution (SLED) modelled by Narayanan & Krumholz (2014), which depends solely on the SFR surface density (} \Sigma_{\text{SFR}} \text{), predicts values of } r_{62} < 0.24 \text{ for typical SFR surface densities of } \lesssim 10 \text{ M}_\odot \text{ yr}^{-1} \text{kpc}^{-2}, \text{ and even for an exceptionally high limit of } \Sigma_{\text{SFR}} = 1000 \text{ M}_\odot \text{ yr}^{-1} \text{kpc}^{-2}, r_{62} > 0.6 \text{ cannot be achieved. Our observed limit for } \Sigma_{\text{SFR}} > 0.6 \text{ could be explained by star formation alone, even at the highest end of the possible } r_{62} \text{ ratio for this source. For } r_{62} < 0.6 \text{ could be explained by star formation alone; however, some contribution of shocks and XDR, possibly powered by the AGN, cannot be ruled out.}
\]

\[
\text{In Fig. 8, we also show the distribution of observed } r_{62} \text{ ratios from Kamenetzky et al. (2016) and Papadopoulos et al. (2012). This shows that the majority of sources are consistent with their CO(6–5) emission being caused by PDR. However, for the galaxies with } r_{62} > 0.24, \text{ it is worth noting that their relatively excited state would require either fairly high SFR surface densities } (>10 \text{ M}_\odot \text{ yr}^{-1} \text{kpc}^{-2}) \text{ or imply the presence of another excitation mechanism (i.e. shocks or XDR). The three most extreme sources in these samples } (r_{62} > 0.6; \text{ IRAS 08572+3915 at 1.1, NGC 34 at 0.92, and 3C 293 at 0.78}) \text{ all have a strong indication that AGN activity is responsible for the abnormally high } r_{62} \text{ (see e.g. Emonts et al. 2005; Floyd et al. 2006; Papadopoulos et al. 2010; Cicone et al. 2014; Mingozzi et al. 2018). Our observed } r_{62} \text{ limits on } r_{62} \text{ could rule out such an extreme AGN excitation as seen in these sources. Unfortunately, our weaker limit on } r_{62} \text{, which, of the three targets observed in CO(6–5), shows the clearest indications of jet activity (Jarvis et al. 2019), does not allow us to place any constraints on the excitation source for the CO(6–5) emission.}
\]

\[
\text{In summary, despite the fact that our targets containing kpc-scale ionized outflows (Fig. 1; Harrison et al. 2014; Jarvis et al. 2019), we}
\]
see no evidence that the CO emission is extremely excited based on the \( L'_{\text{CO}}(6-5)/\text{CO}(2-1) \) ratios. This result is not entirely unexpected. For example, Rosenberg et al. (2015) found that the IR colours of galaxies is a strong predictor of their CO excitation. Based on this, our galaxies (with IRAS 60/100 \( \mu \text{m} \) flux : : : ) should not have highly excited CO. Also, the effect of the AGN is expected to be more clearly seen at \( J > 10 \) (e.g. Mashian et al. 2015; Lu et al. 2017) or at extreme gas densities (e.g. Lamperti et al. 2020). Observations of higher CO transitions could provide a more complete constraint on the influence of the AGN (see e.g. van der Werf et al. 2010; Mashian et al. 2015; Carniani et al. 2019) and spatially resolved observations at multiple CO transitions would enable a study of any localized impact on the gas by the AGN or jets that could be undetectable in the total galaxy-wide emission (see e.g. Dasyra et al. 2016; Zhang et al. 2019).

5.3 The role of AGN in galaxy evolution

Many works have explored the total molecular gas content of AGN host galaxies compared to non-AGN galaxies (e.g. Simpson et al. 2012; Husemann et al. 2017; Kakidak et al. 2017; Perna et al. 2018; Rosario et al. 2018; Kirkpatrick et al. 2019; Shangguan et al. 2020); however, due to the huge amount of variation in the data used, the analysis conducted, and the different selection criteria for comparison samples, creating a unified picture of these results is challenging. The most consistent conclusion seems to be that the molecular gas content for low-redshift (\( z < \approx \) 1) AGN populations is broadly consistent with matched non-AGN galaxies (see e.g. Xia et al. 2012; Krips, Neri & Cox 2012; Villar-Martín et al. 2013).\(^{15}\) Our comparison to non-AGN samples generally supports these broad conclusions: We find, at most, moderate differences in observed or derived molecular gas properties for our quasar sample compared to galaxy samples matched in redshift, stellar mass, \( \text{SFR} \), and \( \Delta_{\text{MS}} \) (see Figs 5 and 6). Additionally, our results suggest that powerful type 2 AGN with signatures of ionized gas outflows and jets reside preferentially in gas-rich starburst galaxies.

In Sections 5.1 and 5.2, we showed that in our sample of local quasars with kpc-ionized gas outflows and jets, there is no indication of AGN feedback having an immediate impact on the total gas reservoir once their distance to the star-forming main sequence is accounted for. These observations, however, are unable to rule out a more localized impact, which can sometimes be observed using spatially resolved molecular gas measurements (e.g. Salomé et al. 2017; Rosario et al. 2018; Fotopoulou et al. 2019; Ramakrishnan et al. 2019; Shin et al. 2019; Lutz et al. 2020). Furthermore, we can not rule out that these processes will have an impact on the global molecular gas supply on longer time-scales. Specific predictions of the typical spatial scales and time frames of the impact on the molecular gas reservoirs are required to test different AGN feedback models (see e.g. Lapi et al. 2014), which has already started to be investigated on host galaxy SFRs (see e.g. Harrison 2017; Scholtz et al. 2018; Schulze et al. 2019).

Figs 6 and 7 indicate that our quasars lie preferentially in molecular gas-rich systems even though our only pre-selections were on the width and luminosity of \( [\text{O} \text{iii}] \) and radio luminosity. Indeed, these systems are more gas-rich, and are more likely to reside in starburst galaxies than less extreme AGN host galaxies (Fig. 7). This is also in qualitative agreement with recent work revealing a relationship between AGN power and offset from the main sequence (at least at \( z \approx 1 \); Bernhard et al. 2019; Grimmett et al. 2020). Although indirectly, our work is consistent with a link between AGN activity and star formation that is driven by the underlying gas content of the host galaxy. Furthermore, similar results have been found in works considering atomic gas and high-redshift sources (see e.g. Ellison et al. 2019; Rodighiero et al. 2019, respectively).

It is worth noting that one of our sources, which is undetected in our APEX data, may be exceptional in that it does have a low gas content. Using the Sun et al. (2014) \( \text{CO}(1-0) \) luminosity of \( L'_{\text{CO}} = 1.03 \times 10^8 \text{K} \text{km} \text{s}^{-1} \text{pc}^2 \) for J1356+1026 would put it amongst the most gas-poor sources in our comparison sample from Tacconi et al. (2018) \( (M_{\text{gas}}/\text{SFR} = 0.05 \text{Gyr}) \) and cause it to fall approximately four times lower than the Sargent et al. (2014) starburst relation (see Fig. 5). This implies either that the luminosity reported in Sun et al. (2014) does not detect all of the diffuse, low-surface-brightness CO emission, or could imply that this source is more rapidly quenched than the rest of our sample. The most obvious exception to this source, which could impact its molecular gas content compared to the rest of the sample, is the double nuclei separated by \( \approx 2.5 \text{ kpc} \) (Greene, Zakamska & Smith 2012), indicating an ongoing merger.

Overall, the observed high molecular gas masses and incidence of starbursts in our sample are consistent with the scenario where the AGN and star formation are linked, and is in broad agreement with simple evolutionary based AGN unification models (see e.g. Sanders et al. 1988; Hopkins et al. 2006; Hickox et al. 2009). Specifically, the well-studied scenario where gas-rich systems have high levels of star formation and obscured/type 2 AGN activity (possibly triggered by mergers), which is followed by feedback processes (such as outflows and jets) that will ultimately quench the AGN activity and star formation in the galaxy. Larger, less biased samples would be needed to confirm these models however. Although we can not be sure of the fate of our galaxies, we may have caught these systems in a special evolutionary phase where the feedback processes are just beginning. We can concretely conclude that the outflows and jets we observe do not rapidly remove the global molecular gas in an appreciable way (i.e. on a time-scale shorter than, or equal to, the observed quasars, jets, or outflows).

Our findings are consistent with many previous studies of the molecular gas and star formation in low-redshift AGN (\( z \approx 0.2 \)). For example, Husemann et al. (2017) find gradually increasing amounts of molecular gas going from AGN in bulge-dominated to disc-dominated to major merger host galaxies and a trend to higher molecular gas masses in systems with more luminous AGN. Similarly, Bertram et al. (2007) find that the Seyferts in their sample have molecular gas content consistent with normal star-forming galaxies, while the powerful quasars are more consistent with starbursts. Luminous AGN are known to generally reside in galaxies with more recent star formation than their lower luminosity counterparts (see e.g. Balmaverde et al. 2016; Bernhard et al. 2019; Grimmett et al. 2020; Kim, Choi & Kim 2020). Finally, there is evidence that obscured AGN lie in more gas-rich systems than their unobscured counterparts (Wylezalek & Zakamska 2016; Rosario et al. 2018) and that the most extreme outflows may be preferentially found in rapidly star-forming, gas-rich systems (see e.g. Rodríguez Zaurín et al. 2013; Harrison et al. 2014; Wylezalek & Zakamska 2016).

To summarize, we find that our sample, selected to be luminous type 2 AGN hosting ionized outflows, lies preferentially in gas-rich galaxies, with high levels of simultaneous star formation, which is consistent with the evolutionary framework described above.
However, the small size of this sample and the two non-detections limit our ability to expand these findings to the quasar population in general. By selecting systems with fast, prominent kpc-ionized gas outflows, we might have expected these outflows to be able to remove the molecular gas, resulting in a deficit. However, the data suggest that if these outflows or jets will ultimately have an impact on the global molecular gas content, it is subtle, or we have captured them too early in the feedback process for this effect to be measurable.

6 CONCLUSIONS

Using APEX observations of the CO(2–1) emission line, we have explored the global molecular gas content of nine $z \sim 0.1$ galaxies selected to host powerful type 2 quasars (log $\left[ L_{\text{AGN}}/\text{erg s}^{-1}\right] \gtrsim 45$) with galaxy-wide ionized outflows and radio jets (see Fig. 1; Harrison et al. 2014; Jarvis et al. 2019). We detected seven of the nine targets in CO(2–1), with corresponding $L_{\text{CO}}(2–1)$ values of $(1.4–7) \times 10^{10}$ K km s$^{-1}$ pc$^2$. For a subset of three targets, we used APEX to obtain upper limits on the CO(6–5)/CO(2–1) emission-line ratios. Our main conclusions are as follows:

(i) For at least seven of the nine quasars in our sample, the total molecular gas reservoirs show no indication of being rapidly depleted due to AGN feedback, despite being selected to have powerful ionized gas outflows and jets. First, we find CO luminosities consistent (within 0.3 dex) with what would be predicted for the general galaxy population given their $L_{\text{IR}}$ and distance to the star-forming main sequence (see Fig. 5 and Section 5.1.1). Second, the derived gas fractions and depletion times of our seven CO(2–1) detected sources (i.e. $M_{\text{gas}}/M_\star \approx 0.1–1.2$ and $M_{\text{gas}}/$SFR$\approx 0.16–0.95$ Gyr, respectively) are comparable to those of redshift-matched non-AGN star-forming galaxies when taking into account their stellar mass, sSFR, and distance from the main sequence (see Fig. 6 and Section 5.1.2).

(ii) Galaxies hosting powerful AGN (i.e. log([O III]/H $\beta$)$>0.6$) tend to have systematically higher gas fractions than those with less powerful AGN and star-forming galaxies in general, when our sample is considered together with those from the xCOLD GASS survey (Saintonge et al. 2017). Galaxies across these samples with the highest gas fractions appear to contain the most powerful AGN and highest levels of concurrent star formation (in relation to the star-forming main sequence; see Fig. 7 and Section 5.1.3).

(iii) The AGN are not having an extreme impact on the global CO excitation in at least two of the three sources for which we have upper limits on the $L_{\text{CO}}(2–1)/L_{\text{IR}}$ ratios (i.e. $r_{62} \lesssim 0.66$; see Fig. 8 and Section 5.2).

In summary, we find that the majority of our sample of quasars have gas-rich, starburst host galaxies, even though we did not select the sample based on these properties. Furthermore, we find that their gas masses are consistent with what would be expected for their observed levels of star formation. There are no signs of an instantaneous depletion of the total molecular gas reservoir by the AGN in our sample, despite their high bolometric luminosities, strong ionized gas outflows, and the presence of kpc-scale jets in many. Our results are consistent with a requirement for high molecular gas fractions to feed both quasar activity and intense periods of star formation. Indeed, by selecting luminous AGN with powerful ionized gas outflows, we may have predominantly selected galaxies in a phase in their evolution where intense star formation and AGN activity are powered by large molecular gas reservoirs and the ‘feedback’ in the form of jets and outflows is relatively young and these processes have not yet had any global impact upon the host galaxies.

Future, higher resolution CO observations and observations of more CO transitions will help determine if these processes have a more subtle and/or localized impact upon the molecular gas properties. Furthermore, galaxy formation models should work towards specific predictions of the molecular gas properties (e.g. gas fractions, depletion times, excitation) to compare to observations, such as ours, to aid understanding of the expected physical scales and time frames of any impact caused by different AGN feedback model prescriptions.

ACKNOWLEDGEMENTS

We thank the referee for their prompt and constructive comments. APEX is a collaboration between the Max-Planck-Institut für Radioastronomie, the European Southern Observatory, and the Onsala Observatory. PJ acknowledges funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme under grant agreement No 724857 (Consolidator Grant ArcheoDyn). DMA acknowledges the support of the UK Science and Technology Facilities Council (STFC) through grants ST/P000541/1 and ST/T00244/1.

DATA AVAILABILITY

APPENDIX A: BAYESIAN FITTING

This section provides further details about our Bayesian fits to our APEX CO observations. The values quoted in Table 3 are derived from these fits. The corner plots showing the posterior probability distributions of each of the parameters for each source are given in the online supplementary data (‘Supplement to Appendix A’; Figs A1–A12).

For the seven CO(2–1) detected targets (see Section 4), we used initial guess parameters from reduced χ² Gaussian fits to the emission-line data using 100 km s⁻¹ bins. For the initial guess parameters for the two CO(2–1) undetected targets (J0958+1439 and J1356+1026), we used the average σ (line width) from the detected targets (170 km s⁻¹) and vₚ ≈ 0. For J0958+1439, we chose an initial guess flux derived from the L_CO−L_IR starburst relation (see Section 5.1.1; f ≈ 6 Jy km s⁻¹) and for J1356+1026, we used the Sun et al. (2014) ALMA CO(1–0) and CO(3–2) total fluxes for a rough estimate (f ≈ 6 Jy km s⁻¹). For the initial guess parameters for fitting the CO(6–5) data, we used the values found through our Bayesian analysis for the CO(2–1) data, multiplying the fluxes by 1.4 to convert into the CO(6–5) transition (for typical LIRGs; Papadopoulos et al. 2012). By fitting sources multiple times with the initial guesses varied by approximately an order of magnitude, we confirmed that the results, within errors do not depend strongly on the initial guess used.

We adopted weak priors for our fitting procedure. We limited the flux and σ_N (noise) to be greater than zero, vₚ, to be within ±2000 km s⁻¹ for CO(2–1) and ±1500 km s⁻¹ for the CO(6–5) data (i.e. the velocity coverage of the data). We constrained σ (line width) to be greater than zero and used slightly different maximum values of σ for different cases. Specifically, for the CO(2–1) detections, we limited the line width to be less than three times the width of the initial guess from the reduced χ² Gaussian fit (corresponding to upper values of 360–680 km s⁻¹), and for the non-detections, we used the largest limit from the detected lines (i.e. σ ≤ 680 km s⁻¹). For the CO(6–5) data, we limited σ (line width) to be less than three times the CO(2–1) line width from this Bayesian analysis (i.e. the values quoted in Table 3). We note that using more complicated or more constraining priors could lower the errors on our fits and our upper limits; however, this would risk introducing bias into the results.

Our fitting code is designed to be completely general and therefore, our likelihood is composed of a single Gaussian with both Poisson and Gaussian noise considered. However, Poisson and Gaussian likelihoods become indistinguishable even for very moderate values of the mean parameter (>10). Our priors are uniform distributions that drop to 0 outside of the bounds described above. We use 100 walkers for the MCMC analysis and run it for 500 steps with the first 300 steps later cropped as burn in (visual inspection of the trace plots were used to confirm the burn in period for all fits). We determine the starting position for each walker using the initial guesses described above with a random offset added drawn from a uniform distribution limited to within ±3 orders of magnitude less than the initial guess.

For each source where the CO(2–1) line is detected (all except J0958+1439 and J1356+1026), the posterior distributions for all four parameters show clear peaks. In contrast, the non-detections do not show clear peaks in one or more of the parameters (the posteriors for σ in particular do not have clear peaks for any of the non-detected CO lines; see corner plots in online ‘Supplement to Appendix A’). Further details on the individual fits can be found in the corner plots and captions in Figs A1–A12.

APPENDIX B: α_Co AND MOLECULAR GAS MASS CALCULATIONS

Here we provide specific details about how we calculated α_CO and the molecular gas masses. We also present these derived values for each source, using the two different methods that are discussed in this paper (see Table B1). In each case, r₂₁ = 0.8 is used to convert from CO(2–1) into CO(1–0) (see Section 5.1.2).

For a comparison with the values from Tacconi et al. (2018) (Section 5.1.2 and Fig. 6), we follow the α_CO calculation from that work (as in Genzel et al. 2015), taking the geometric mean of the metallicity-dependent α_CO recipes of Bolatto et al. (2013) and Genzel et al. (2012):

\[
\alpha_{\text{CO}} = 4.36 \times 0.67 \times \exp(0.36 \times 10^{-0.1(12+\log(O/H)-8.67)} \times 10^{(-1.27 \times (12+\log(O/H)-8.67))})
\]

(B1)

where α_CO has units M_☉ (K km s⁻¹ pc²)⁻¹. Also, following Tacconi et al. (2018), we use the following mass-metallicity relation from Genzel et al. (2015):

\[
12 + \log(O/H) = a - 0.807 \times (\log(M_* - b))^2,
\]

(B2)

where \(a = 8.74\) and \(b = 10.4 + 4.46 \times \log(1+z) - 1.78 \times (\log(1+z))^2\).

(B3)

For the comparison with the xCOLD GASS samples in Section 5.1.3, we calculate α_CO following Saintonge et al. (2017). Specifically, they use the metallicity- and ΔMS-dependent α_CO correlation from Accurso et al. (2017):

\[
\log(\alpha_{\text{CO}}) = 14.752 - 1.623 \times [12 + \log(O/H)] + 0.062 \times \log(\Delta_{\text{MS}}).
\]

(B4)

To keep consistent with the methods adopted in the comparison sample, we calculate the metallicity (12+log(O/H)) following the Pettini & Pagel (2004) ‘O3N2’ consistent mass–metallicity relation
**Table B1.** The values $\alpha_{\text{CO}}$ and $M_{\text{gas}}$ for each source in this sample using the two methods used in this work to be consistent with the literature comparisons.

| Name          | Tacconi et al. comparison (Fig. 6) | xCOLD GASS comparison (Fig. 7) |
|---------------|----------------------------------|--------------------------------|
|               | $\alpha_{\text{CO}}$ (2) | $\log M_{\text{gas}}/M_\odot$ (3) | $\alpha_{\text{CO}}$ (4) | $\log M_{\text{gas}}/M_\odot$ (5) |
| J0945+1737    | 4.1                          | 10.07$^{+0.1}_{-0.08}$ | 5.3 | 10.18$^{+0.1}_{-0.08}$ |
| J0958+1439    | 4.0                          | <10.0 | 3.4 | <10.0 |
| J1000+1242    | 4.2                          | 9.99$^{+0.08}_{-0.06}$ | 6.0 | 10.14$^{+0.08}_{-0.06}$ |
| J1010+1413    | 4.1                          | 10.54$^{+0.07}_{-0.06}$ | 3.7 | 10.5$^{+0.07}_{-0.06}$ |
| J1010+0612    | 4.0                          | 10.03$^{+0.1}_{-0.09}$ | 3.9 | 10.01$^{+0.1}_{-0.09}$ |
| J1100+0846    | 4.0                          | 10.15$^{+0.08}_{-0.06}$ | 3.7 | 10.1$^{+0.08}_{-0.06}$ |
| J1316+1753    | 4.1                          | 10.1$^{+0.2}_{-0.1}$ | 3.7 | 10.1$^{+0.2}_{-0.1}$ |
| J1356+1026    | 4.0                          | <10.0 | 3.9 | <10.0 |
| J1430+1339    | 4.1                          | 9.9$^{+0.2}_{-0.1}$ | 3.3 | 9.8$^{+0.2}_{-0.1}$ |

**Notes:** (1) Object name; (2) $\alpha_{\text{CO}}$ calculated to be consistent with Tacconi et al. (2018); (3) $\log M_{\text{gas}}$ calculated to be consistent with Tacconi et al. (2018); (4) $\alpha_{\text{CO}}$ calculated to be consistent with xCOLD GASS (Saintonge et al. 2017); (5) $\log M_{\text{gas}}$ calculated to be consistent with xCOLD GASS (Saintonge et al. 2017).

\[ 12 + \log \frac{\text{O}}{\text{H}} = a + b \times \log M_\star + c \times \log M_{\star}^2 + d \times \log M_{\star}^3, \]

where $a = 32.1488$, $b = -8.51258$, $c = 0.976384$, $d = -0.0359763$, and $M_\star$ is in $M_\odot$. For additional consistency we do not use the $\Delta_{\text{MS}}$ (i.e. the ratio of the sSFR of the galaxy and its local main sequence) derived in the main paper, but re-calculate this value for use in the $\alpha_{\text{CO}}$ calculation, using the same method as in Saintonge et al. (2017). That is, using the star-forming main sequence from Accurso et al. (2017):

\[ \log \text{sSFR}_{\text{MS}}[\text{Gyr}] = -1.12 + 1.14 \times z - 0.19 \times z^2 - (0.3 + 0.13 \times z)(\log M_\star - 10.5). \]

As described in Accurso et al. (2017), this $\alpha_{\text{CO}}$ relation is only valid within $7.9 < 12 + \log \left( \frac{\text{O}}{\text{H}} \right) < 8.8$ and $-0.8 < \log \Delta_{\text{MS}} < 1.3$. Using the $\Delta_{\text{MS}}$ values for these calculations, J0945+1737, J1000+1242, and J1356+1026 all fall outside (or at the edge of) of the allowed $\Delta_{\text{MS}}$ range (with $\log \Delta_{\text{MS}} = 1.6, 1.4$, and 1.3, respectively). However, using the recommended starburst $\alpha_{\text{CO}}$ from Accurso et al. (2017) of one for these sources does not change the conclusions of this work.

We note that the gas masses derived from both of the methods described above are consistent within errors.
List of astronomical key words (Updated on 2020 January)

This list is common to Monthly Notices of the Royal Astronomical Society, Astronomy and Astrophysics, and The Astrophysical Journal. In order to ease the search, the key words are subdivided into broad categories. No more than six subcategories altogether should be listed for a paper.

The subcategories in boldface containing the word ‘individual’ are intended for use with specific astronomical objects; these should never be used alone, but always in combination with the most common names for the astronomical objects in question. Note that each object counts as one subcategory within the allowed limit of six.

The parts of the key words in italics are for reference only and should be omitted when the keywords are entered on the manuscript.
