EFFECT OF LASER PHOTOCOAGULATION ON MACULAR EDEMA ASSOCIATED WITH MACULAR HOLES

Anibal Francone, MD,* Juliet Essilfe, MD,† David Sarraf, MD,‡ Rony C. Preti, MD, PhD,§ Mario L. R. Monteiro, MD, PhD,§ Jean-Pierre Hubschman, MD*

Purpose: To report the outcomes of laser therapy to barricade eccentric full-thickness macular hole with associated cystoid macular edema.

Methods: We report two patients who developed an eccentric full-thickness macular hole with persistent cystoid macular edema after pars plana vitrectomy with and without internal limiting membrane peel for epiretinal membrane and the results of argon laser therapy.

Results: Barricade argon laser therapy was applied concentric to the full-thickness macular hole. Associated cystoid macular edema was noted to resolve within 1 to 3 months of therapy in both cases.

Conclusion: Barricade laser therapy surrounding a macular hole can lead to resolution of associated cystoid macular edema. Pathogenic mechanisms to explain this favorable outcome are discussed.

RETINAL CASES & BRIEF REPORTS 15:730–733, 2021

From the *Division of Retina, Stein Eye Institute, University of California Los Angeles Geffen School of Medicine, Los Angeles, CA; †Stein Eye Institute, Department of Ophthalmology, University of California Los Angeles Geffen School of Medicine, Los Angeles, CA; ‡Stein Eye Institute, Department of Ophthalmology, University of California, David Geffen School of Medicine, Los Angeles (UCLA), California; VA Greater Los Angeles Healthcare System, Los Angeles, California; and §Division of Ophthalmology, University of São Paulo Medical School, Sao Paulo, Brazil.

Eccentric macular hole (MH) is a rare but established complication after pars plana vitrectomy with or without internal limiting membrane peel (PPV/ILM) and may occur in 0.3 to 6% of cases after PPV for various macular disorders including epiretinal membrane, MH, and persistent cystoid macular edema (CME).1–3 The pathophysiology of eccentric MH formation has yet to be elucidated. Proposed theories include contraction of the persistent ILM, secondary epimacular proliferation stimulated by the ILM peel, and iatrogenic traction to the retina with the forceps during membrane peeling.4–6

Eccentric MHs are generally stable without vision loss but can be complicated by CME.2 We present two cases of eccentric MH formation, after PPV with and without ILM peel, complicated by CME that resolved after treatment with laser retinopexy to barricade the iatrogenic MH.

Case Reports

Case 1

A 71-year-old woman presented to the Stein Eye Institute for management of visually significant CME associated with iatrogenic eccentric MH formation in the right eye. Ocular history was notable for PPV/ILM for epiretinal membrane and macular pucker in the right eye 6 months earlier. Shortly after surgery, the patient developed significant CME that was persistent despite two intravitreal triamcinolone injections. Ocular history included bilateral uncomplicated cataract extraction with lens implantation a few years before presentation.

On examination, best-corrected visual acuity was 20/70 in the right eye and 20/20 in the left eye. Dilated retinal examination demonstrated an iatrogenic full-thickness eccentric MH temporal to the macula of the right eye. Macular spectral domain optical coherence tomography of
the right eye illustrated severe CME extending from the MH to the fovea (Figure 1A). The edema and hole were stable for several months and unimproved after intravitreal steroid injection when compared with previous imaging from the referring ophthalmologist. Due to recalcitrant CME, the decision was made to barricade the MH with argon laser therapy (PASCAL Topcon Corporation, Japan). The laser parameters applied included a power of 300 mW, a pulse duration of 300 ms, a spot size of 200 \( \mu \text{m} \), and a total number of 181 shots. The patient was pretreated with one 1.25-mg/0.05-mL bevacizumab injection to reduce retinal edema around the hole and improve laser energy absorption. Vision improved, and the CME resolved within 3 months of the laser procedure (Figure 1B). Best-corrected visual acuity remained at 20/30 with continued resolution of fluid at the most recent follow-up, 1 year after laser treatment.

Case 2

A 70-year-old woman was evaluated at the University of São Paulo for management of chronic CME after extracapsular cataract surgery of the left eye. Of note, she presented with a history of PPV for epiretinal membrane of the left eye that was complicated by a full-thickness eccentric MH (Figure 2). Best-corrected visual acuity was 20/50 in the left eye. Treatment with one intravitreal triamcinolone acetonide (0.1 mL/4 mg) and two intravitreal bevacizumab (1.25 mg/0.05 mL) injections over the course of 5 months was not associated with any visual or anatomical improvement. Given the persistent CME, the decision was made to barricade the eccentric MH with argon laser therapy (PUREPOINT 532 nm; Alcon Laboratories, Inc, Fort Worth, TX). The laser parameters applied included a power of 250 mW, a duration of 0.1 ms, and a spot size of 150 \( \mu \text{m} \). One month after laser treatment, the CME was nearly resolved and vision was improved to 20/25 in the left eye (Figure 3). Of note, the patient’s last anti–vascular endothelial growth factor treatment was 10 months before the laser treatment.
Discussion

Eccentric MH formation after PPV/ILM is an unusual complication. Patients are typically asymptomatic and the risk of retinal detachment is negligible.2,7 Prophylactic laser retinopexy to decrease the low risk of retinal detachment may be considered in some cases.

Severe CME may complicate a postoperative eccentric MH; however, the pathogenesis of fluid accumulation associated with MH formation remains unclear. Possible mechanisms for CME development include postsurgical inflammation or persistent fluid after ILM peel. Alternatively, the cystic abnormalities may represent degenerative cavitation, possibly related to Muller cell disruption, as recently proposed.8 Hydration of the retina from the vitreous through the MH (Figure 4) versus disruption and leakage of the deep retinal capillary plexus have also been proposed.9,10 Retinal pigment epithelium decompensation may serve to further complicate these hydrostatic mechanisms. The pattern of edema on the macular thickness map in our cases suggested a mechanism of vitreous hydration as the fluid localized around the hole with a linear tract of edema extending from the hole to the fovea in both cases (Figure 5). This configuration is similar to the pattern of fluid secondary to an optic nerve pit.

Both patients were treated with barricade laser therapy. The goal of the laser treatment was to create a strong adherence between the retinal pigment epithelium and neuroretina and induce local scarring to block fluid movement through the interstitial retinal tissue. Consequently, a stronger laser setting (higher power and longer duration) was implemented than is typical for a routine retinopexy.11 After laser therapy, the CME briskly resolved in each case, perhaps the result of a barricade effect of the retinal scar (Figures 3 and 6), suggesting that vitreous hydration of the retina may be the etiology of CME. Mild cystoid fluid persisted inside the zone of laser scars where a patent conduit of vitreous fluid was still present, which may be further evidence of the barricade effect of the laser therapy.

Nevertheless, we cannot exclude the possibility that the laser energy exerted a cellular or microvascular effect leading to resorption of intraretinal fluid.12 Focal macular laser photocoagulation for diabetic macular edema and other retinal vascular disorders associated with CME has been an important modality of therapy for many years, and various mechanisms have been

proposed to explain the deturgescence effect of the laser energy on the retina including retinal vascular endothelial turnover and retinal pigment epithelium pump enhancement.\textsuperscript{13}

More robust investigation with larger numbers of patients and longer follow-up will help to elucidate the mechanism of fluid resolution in these cases. However, the creation of a laser photocoagulation full-thickness barricade around the hole may be considered for the treatment of severe CME complicating eccentric MH formation.
