Abstract

Unsupervised multi-object scene decomposition is a fast-emerging problem in representation learning. Despite significant progress in static scenes, such models are unable to leverage important dynamic cues present in video. We propose a novel spatio-temporal iterative inference framework that is powerful enough to jointly model complex multi-object representations and explicit temporal dependencies between latent variables across frames. This is achieved by leveraging 2D-LSTM, temporally conditioned inference and generation within the iterative amortized inference for posterior refinement. Our method improves the overall quality of decompositions, encodes information about the objects’ dynamics, and can be used to predict trajectories of each object separately. Additionally, we show that our model has a high accuracy even without color information. We demonstrate the decomposition, segmentation, and prediction capabilities of our model and show that it outperforms the state-of-the-art on several benchmark datasets, one of which was curated for this work and will be made publicly available.

1 Introduction

Unsupervised representation learning, which has a long history dating back to Boltzman Machines [22] and original works of Marr [33], has recently emerged as one of the important directions of research, carrying the newfound promise of alleviating the need for excessively large and fully labeled datasets. More traditional representation learning approaches focus on unsupervised (e.g., autoencoder-based [35, 45]) or self-supervised [34, 46, 50] learning of holistic representations that, for example, are tasked with producing (spatial [34], temporal [46], or color [50]) encodings of images or patches. The latest and most successful methods along these lines include ViLBERT [31] and others [41, 42] that utilize powerful transformer architectures [44] coupled with proxy multi-modal tasks (e.g., masked token prediction or visual-lingual alignment). Learning of good disentangled, spatially granular, representations that are, for example, able to decouple object appearance and shape in complex visual scenes consisting of multiple moving objects remains elusive.

Recent works that attempt to address this challenge can be characterized as: (i) attention-based methods [8, 11], which infer latent representations for each object in a scene, and (ii) iterative refinement models [17, 19], which decompose a scene into a collection of components by grouping pixels. Importantly, the former have been limited to latent representations at object- or image patch-levels, while the latter class of models have illustrated the ability for more granular latent representations at the pixel (segmentation)-level. Specifically, most refinement models learn pixel-level generative models driven by spatial mixtures [19] and utilize amortized iterative refinements [32] for inference of disentangled latent representations within the VAE framework [28]: a prime example is IODINE [17]. However, while providing a powerful model and abstraction which is able to segment

*This work was done during an internship at Borealis AI. Correspondence to pzablots@cs.ubc.ca.
Unsupervised Video Decomposition. Our approach allows to infer precise segmentations of the objects via interpretable latent representations, that can be used to decompose each frame and simulate the future dynamics, all in unsupervised fashion. Whenever a new object emerges into a frame the model dynamical adapts and uses one of the segmentation slots to assign to the new object.

and disentangle complex scenes, IODINE [17] and other similar architectures are fundamentally limited by the fact that they only consider images. Even when applied for inference in video, they process one frame at a time. This makes it excessively challenging to discover and represent individual instances of objects that may share properties such as appearance and shape but differ in dynamics.

In computer vision, it has been a long-held belief that motion carries important information for segmenting objects [25, 48]. Armed with this intuition, we propose a spatio-temporal amortized inference model capable of not only unsupervised multi-object scene decomposition, but also of learning and leveraging the implicit probabilistic dynamics of each object from perspective raw video alone. This is achieved by introducing temporal dependencies between the latent variables across time. As such, IODINE [17] could be considered a special (spatial) case of our spatio-temporal formulation. Modeling temporal dependencies among video frames also allows us to make use of conditional priors [6] for variational inference, leading to more accurate and efficient inference results. The resulting model, illustrated in Fig. 1, achieves superior performance on complex multi-object benchmarks with respect to state-of-the-art models, including R-NEM [43] and IODINE [17].

Contributions. We propose a new spatio-temporal amortized inference model that is not only capable of multi-object video decomposition in an unsupervised manner but also learns and models the probabilistic dynamics of each object from complex raw video data by leveraging temporal dependencies between the latent random variables at each frame. To the best of our knowledge this is the first spatio-temporal model of this kind. Our model has a number of appealing properties, including temporal extrapolation (prediction), computational efficiency, and the ability to work with complex data exhibiting non-linear dynamics, colors, and changing number of objects within the same video sequence (e.g., due to objects exiting and entering the scene). In addition, we introduce an entropy prior to improve our model’s performance in scenarios where object appearance alone is not sufficiently distinctive (e.g., greyscale data). Finally, we illustrate state-of-the-art performance on challenging multi-object benchmark datasets (Bouncing Balls and CLEVRER), outperforming results of R-NEM [43] and IODINE [17] in terms of segmentation, prediction, and generalization.

2 Related work

Unsupervised Scene Representation Learning. Unsupervised scene representation learning has a rich history. Generally, these methods can be divided into two groups: attention-based methods, which infer latent representations for each object in a scene, and more complex and powerful iterative refinement models, which often make use of spatial mixtures and can decompose a scene into a collection of precisely estimated components by grouping pixels together. Attention-based methods, such as AIR [11] and SPAIR [8], decompose scenes into latent variables representing the appearance, position, and size of the underlying objects. However, both methods can only infer the objects’ bounding boxes (not segmentations) and have not been shown to work on non-trivial 3D scenes with perspective distortions and occlusions. MoNet [2] is the first model in this family tackling more complex data and inferring representations that can be used for instance segmentation of the objects and individual reconstructions. On the other hand, it is not a probabilistic generative model and thus not suitable for density estimation. GENESIS [10] extends MoNet and alleviates some of its limitations by introducing a probabilistic framework and allowing for spatial relations between the objects. Iterative refinement models started with Tagger [18] that explicitly reasons about the segmentation of its inputs and features. However, it does not allow explicit latent representations and cannot be scaled to larger and more complex images. NEM [19], as an extension of Tagger,
uses a spatial mixture model inside an expectation maximization framework but is limited to binary data. Finally, IODINE [17] is a notable example of a model employing iterative amortized inference w.r.t. a spatial mixture formulation and achieves state-of-the-art performance in scene decomposition and segmentation. Furthermore, it can cope with complex data, including occlusions, and uses an auxiliary component to separate the objects from the background.

Unsupervised Video Tracking and Object Detection. SQAIR [29], SILOT [7] and SCALOR [26] are temporal extensions of the static attention-based models that are tailored to tracking and object detection tasks. SQAIR is restricted to binary data and operates at the level of bounding boxes. SILOT and SCALOR are more expressive and can cope with cluttered scenes, a larger numbers of objects, and dynamic backgrounds but do not work on colored perspective data; accurate segmentation remains a challenge. Finally, STOVE [30] focuses on physics-driven learning and simulation.

Unsupervised Video Decomposition and Segmentation. Models employing spatial mixtures and iterative inference in a temporal setting are closest to our method from a technical perspective. Notably, there are only few models falling into this line of work: RTagger [35] is a recurrent extension of Tagger but inherits the limitations of its predecessor. R-NEM [43] effectively learns the objects’ dynamics and interactions through a relational module but is limited to orthographic binary data.

Non-representation Learning Methods. Orthogonal to unsupervised representation learning for instance segmentation and object detection are methods relying on fully labeled data, including Mask R-CNN [20], Yolo V3 [38], and Fast R-CNN [13]. Alternatively, hand-crafted features can be used, as demonstrated in [12, 40]. Unsupervised video segmentation also plays an important role in reinforcement learning: MOREL [14] takes an optical flow approach to segment the moving objects, while others use RL agents to infer segmentations [3].

3 Dynamic Video Decomposition

We now introduce our dynamic model for unsupervised video decomposition. Our approach builds upon a generative model of multi-object representations [17] and leverages elements of iterative amortized inference [32]. We briefly review both concepts (§3.1) and then introduce our model (§3.2).

3.1 Background

Multi-Object Representations. The multi-object framework introduced in [17] decomposes a static image $x = (x_i)_{i \in D}$ into $K$ objects (including background). Each object is represented by a latent vector $z^{(k)} \in \mathbb{R}^{K}$ capturing the object’s unique appearance and can be thought of as an encoding of common visual properties, such as color, shape, position, and size. For each $z^{(k)}$ independently, a broadcast decoder [47] generates pixelwise pairs $(m_i^{(k)}, \mu_i^{(k)})$ describing the assignment probability and appearance of pixel $i$ for object $k$. Together, they induce the generative image formation model

$$p(x | z) = \prod_{i=1}^{D} \sum_{k=1}^{K} m_i^{(k)} \mathcal{N}(x_i; \mu_i^{(k)}, \sigma^2), \quad (1)$$

where $z = (z^{(k)})_{k}$, $\sum_{k=1}^{K} m_i^{(k)} = 1$ and $\sigma$ is the same and fixed for all $i$ and $k$. The original image pixels can be reconstructed from this probabilistic representation as $\tilde{x}_i = \sum_{k=1}^{K} m_i^{(k)} \mu_i^{(k)}$.

Iterative Amortized Inference. Our approach leverages the iterative amortized inference framework [32], which uses the learning to learn principle [11] to close the amortization gap [21] typically observed in traditional variational inference. The need for such an iterative process arises due to the multi-modality of Eq. (1), which results in an order invariance and assignment ambiguity in the approximate posterior that standard variational inference cannot overcome [17].

The idea of amortized iterative inference is to start with randomly guessed parameters $\lambda^{(k)}_1$ for the approximate posterior $q_{\lambda^{(k)}_1}(z^{(k)}_1 | x)$ and update this initial estimate through a series of $R$ refinement steps. Each refinement step $r \in \{1, \ldots, R\}$ first samples a latent representation from $q_{\lambda}$ to evaluate the ELBO $\mathcal{L}$ and then uses the approximate posterior gradients $\nabla_{\lambda} \mathcal{L}$ to compute an additive update

---

2 Perspective videos are more complex as objects can occlude one another and change in size over time.
we can formalize this new update scheme as follows:
\[ z_{t+1}^{(k)} \approx q_{\lambda}(z_{t+1}^{(k)} | x), \quad \lambda_{t+1}^{(k)} \leftarrow \lambda_{t}^{(k)} + f_{\phi}(a^{(k)}, h_{t-1}^{(k)}), \]
where \(a^{(k)}\) is a function of \(z_{t-1}^{(k)}, x, \nabla_{\lambda} L\), and additional inputs. The function \(f_{\phi}\) consists of a sequence of convolutional layers and an LSTM. The memory unit takes as input a hidden state \(h_{t-1}^{(k)}\) from the previous refinement step.

3.2 Spatio-Temporal Iterative Inference

Our proposed model builds upon the concepts introduced in the previous section and enables robust learning of dynamic scenes through spatio-temporal iterative inference. Specifically, we consider the task of decomposing a video sequence \(x = (x_t)_{t=1}^{T} = (x_{t,i})_{t,i=1}^{T,D}\) into \(K\) slot sequences \((m_i^{(k)})_t\) and \(K\) appearance sequences \((\mu_i^{(k)})_t\). To this end, we introduce explicit temporal dependencies into the sequence of posterior refinements and show how to leverage this contextual information during decoding with a generative model. The resulting computation graph can be thought of as a 2D grid with time dimension \(t\) and refinement dimension \(r\) (Fig. 2a). Propagation of information along these two axes is achieved with a 2D-LSTM [16] (Fig. 2b), which allows us to model the joint probability over the entire video sequence inside the iterative amortized inference framework. The proposed method is expressive enough to model the multimodality of our image formation process and posterior, yet its runtime complexity is smaller than that of its static counterpart.

3.2.1 Variational Objective

Since exact likelihood training is intractable, we formulate our task in terms of a variational objective. In contrast to traditional optimization of the evidence lower bound (ELBO) through static encodings of the approximate posterior, we incorporate information from two dynamic axes: (1) variational estimates from previous refinement steps; (2) temporal information from previous frames. Together, they form the basis for spatio-temporal variational inference via iterative refinements. Specifically, we train our model by maximizing the following ELBO objective:

\[ L_{\text{ELBO}}(x) = \mathbb{E}_{q_{\lambda}(x \leq T, \bar{R} \mid x \leq T)} \sum_{t=1}^{T} \sum_{r=1}^{R} \left[ \beta \log \left( p(x_t \mid x_{<t}, z_{\leq t,r}) \right) - \text{KL}(q_{\lambda}(z_{t,r} \mid x_{<t}, z_{<t,r}) \parallel p(z_t \mid x_{<t}, z_{<t})) \right], \]

where the first term expresses the reconstruction error of a single frame and the second term measures the divergence between the variational posterior and the prior. The relative weight between terms is controlled with a hyperparameter \(\beta\) [21]. Furthermore, to reduce the overall complexity of the model and to make it easier to train, we set \(\bar{R} := \max(R - t, 1)\) (see Fig. 2a for an illustration). Compared to a static model, which infers each frame independently, reusing information from previous refinement steps also makes our model more computationally efficient. In the next sections, we discuss the form of the conditional distributions in Eq. (3) in more detail.

3.2.2 Inference and Generation

Posterior Refinement. Optimizing Eq. (3) inside the iterative amortized inference framework (Section 3.1) requires careful thought about the nature and processing of the hidden states. While there is vast literature on the propagation of a single signal, including different types of RNNs [23, 4, 15, 5] and transformers [44], the optimal solution for multiple axes with different semantic meaning (i.e., time and refinements) is less obvious. Here, we propose to use a 2D version of the uni-directional MD-LSTM [16] to compute our variational objective (Eq. (3)) in an iterative manner. In order to do so, we replace the traditional LSTM in the refinement network (Eq. (2)) with a 2D extension. This extension allows the posterior gradients to flow through both the grid of the previous refinements and the previous time steps (see Fig. 2a). Writing \(z_{t,r}\) for the latent encoding at time \(t\) and refinement \(r\), we can formalize this new update scheme as follows:

\[ z_{t,r} \sim q_{\lambda}(z_{t,r} \mid x_{\leq t}, z_{<t,r}), \quad \lambda_{t+1} \leftarrow \lambda_{t} + f_{\phi}(a, h_{t-1}, h_{t-1,r}). \]

For simplicity, we drop references to the object slot \(\bullet^{(k)}\) from now on and formulate all equations on a per-slot basis.
Model Overview. (a) Inference in our model passes through a 2D grid in which light gray cell \((r, t)\) represents the \(r\)-th refinement at time \(t\), dark gray cells are where the final reconstruction is computed and no refinement is needed. Each light gray cell receives three inputs: a refinement hidden state \(h_{t-1,r}\), a temporal hidden state \(h_{t-1}\), and posterior parameters \(\lambda_{t,r}\). The outputs are a new hidden state \(h_{t,r}\) and new posterior parameters \(\lambda_{t,r+1}\). (b) An example of the internal structure of the highlighted cell from Fig. (a). We process the inputs with the help of a spatial broadcast decoder \([17]\) and a 2D LSTM \([16]\). The rest of the light gray cells have the same structure.

Temporal Conditioning. Inside the learning objective we set the prior and the likelihood to be conditioned on the previous frames and the refinement steps. This naturally comes from an idea that each frame is dependent on the predecessor’s dynamics and therefore latent representations should follow the same property. Conditioning on the refinement steps is essential to the iterative amortized inference procedure. To model the prior and the likelihood distributions accordingly we adopt the approach proposed in Chung et al. \([6]\) but tailor it to our iterative amortized inference setting. Specifically, the parameters of our Gaussian prior are now computed from the temporal hidden state \(h_{t-1}\):

\[
p(z_t|x_{<t}, z_{<t}) = \mathcal{N}(z_t; \tilde{\mu}_t, \text{diag}(\tilde{\sigma}_t^2)), \quad [\tilde{\mu}_t, \tilde{\sigma}_t] = \xi_\theta(h_{t-1,R}),
\]

where \(\xi_\theta\) is a simple neural network with a few layers\(^4\). Please refer to the supplemental material for details. Note that the prior only changes along the time dimension and is independent of the refinement iterations, because we refine the posterior to be as close as possible to the dynamic prior for the current time step. Finally, to complete the conditional generation, we modify the likelihood distribution as follows:

\[
p(x_t|x_{<t}, z_{<t,r}) = \prod_{i=1}^D \sum_{k=1}^K m_{t,r,i}^{(k)} \mathcal{N}(x_{t,i}; \mu_{t,r,i}^{(k)}, \sigma_i^2), \quad [m_{t,r,i}^{(k)}, \mu_{t,r,i}^{(k)}] = g_\theta(z_{t,r}^{(k)}, h_{t-1,R}^{(k)}),
\]

where \(\mu_{t,r,i}^{(k)}, m_{t,r,i}^{(k)}\) are mask and appearance of pixel \(i\) in slot \(k\) at time step \(t\) and refinement step \(r\). \(g_\theta\) is a spatial mixture broadcast decoder \([17]\) with preceding MLP to transform the pair \((z_{t,r}^{(k)}, h_{t-1,R}^{(k)})\) into a single vector representation.

Learning and Prediction

Architecture. From a graphical point of view, we can think of the refinement steps and time steps as being organized on a 2D grid from Fig. 2a with light gray cell \((r, t)\) representing the \(r\)-th refinement at

\(^4\)In practice, \(\xi_\theta\) predicts \(\log \sigma_t\) for stability reasons.

\(^5\)Since our likelihood is a Gaussian mixture model, we are now referencing the object slot \(\bullet^{(k)}\) again.
time \( t \). According to Eq. (1), each such cell takes as input the hidden state from a previous refinement \( h_{t-1,r} \), the temporal hidden state \( h_{t-1,R} \), and the posterior parameters \( \lambda_{t,r} \). Outputs of each light gray cell are new posterior parameters \( \lambda_{t,r+1} \) and a new hidden state \( h_{t,r} \). At the last refinement \( R \) at time \( t \), the value of the refinement hidden state \( h_{t,r} \) is assigned to a new temporal hidden state \( h_{t,R} \).

**Training Objective.** Instead of a direct optimization of Eq. (3), we propose two modifications that we found to improve our model’s practical performance: (1) similar to observations made by Greff et al. [17], we found that color is an important factor for high-quality segmentations. In the absence of such information, we mitigate the arising ambiguity by maximizing the entropy of the masks \( m_{t,r,i}^{(k)} \) along the slot dimension \( k \), i.e., we train our model by maximizing the objective

\[
\mathcal{L}_{\text{ELBO}} + \gamma \sum_{i=1}^{D} \sum_{k=1}^{K} m_{t,r,i}^{(k)} \log(m_{t,r,i}^{(k)}),
\]

where \( \gamma \) defines the weight of the entropy loss. (2) In addition to the entropy loss, we also prioritize later refinement steps by weighting the terms in the inner sum of Eq. (3) with \( \frac{1}{R} \).

**Prediction.** On top of pure video decomposition, our model is also able to simulate future frames \( x_{T+1}, \ldots, x_{T+T'} \). Because our model requires image data \( x_t \) as input, which is not available during simulation of new frames, we use the reconstructed image \( \hat{x}_t \) in place of \( x_t \) to compute the likelihood \( p(x_t|x_{<t}, z_{\leq t}) \) in these cases. We also set the gradients \( \nabla_{\lambda} L, \nabla_{\mu} L, \) and \( \nabla_m L \) to zero.

**Complexity.** Our model’s ability to reuse information from previous refinements leads to a runtime complexity of \( \mathcal{O}(R^2 + T) \), which is much more efficient than the \( \mathcal{O}(RT) \) complexity of the traditional IODINE model [17] (when each frame is inferred independently) in the typical case of \( T \gg R \).

## 4 Experiments

We validate our model on Bouncing Balls [43] and an augmented version of CLEVRER [49]. Our experiments comprise quantitative studies of decomposition quality during generation and prediction as well as an ablation study. We complement these results with visual illustrations. An additional wide range of visualizations and experimental details can be found in the supplemental material.

### 4.1 Setup

**Datasets.** Bouncing Balls consists of 50 frame, binary, \( 64 \times 64 \) resolution video sequences. Each video shows simulated balls with different masses bouncing elastically off each other and the image border. We train our model on the first 40 frames of 50K videos containing 4 balls in each frame. We use two different test sets consisting of 10K videos with 4 balls and 10K videos with 6-8 balls. We also validate our model on a color version of this dataset that we generate using the segmentation masks.

CLEVRER contains synthetic videos of moving and colliding objects. Each video is 5 seconds long (128 frames) at resolution of \( 480 \times 320 \), which we trim and rescale to \( 64 \times 64 \) pixels (see supp. mat.). For training, we use the same 10K videos as in the original source. For testing, we compute ground truth masks for the validation set using the provided annotations and test on 2.5K instances containing 3-5 objects and on 1.1K instances containing 6 objects. We set the number of slots \( K \) to 6 for the CLEVRER training set and to one more than the maximum number of objects in all other cases.

**Baselines.** We compare our approach to two recent baselines: R-NEM [43] and IODINE [17]. R-NEM is a state-of-the-art model for unsupervised video decomposition and physics learning. While showing impressive results on simulation tasks, it is limited to binary data and has difficulties with perspective scenes. IODINE is more expressive but static in nature and cannot capture temporal dynamics within its probabilistic framework. However, as noted in [17], it can be readily applied to temporal sequences by feeding a new video frame to each iteration of the LSTM in the refinement network. We call this variant SEQ-IODINE and compare to it as well.

### 4.2 Evaluation Metrics

**ARI.** The Adjusted Rand Index [37, 24] is a measure of clustering similarity. It is computed by counting all pairs of samples that are assigned to the same or different clusters in the predicted and
Table 1: **Quantitative Evaluation (Scene Decomposition).** We show our model’s ability to produce high-quality instance segmentations for sequences with varying length. We test on sequences with 4 balls and two different types of data (binary, colored) for Bouncing Balls and on sequences with 3-5 objects for CLEVRER. Note, R-NEM does not cope with color data; hence we only run it on binary.

Figure 3: **Qualitative Evaluation (Bouncing Balls).** Our model can generalize to sequences with 8 balls when trained on 4 balls. Top-to-bottom: output masks, reconstructions, and ground truth video.

true clusterings. It ranges from -1 to 1, with score of 0 indicating a random clustering and 1 indicating a perfect match. We treat each pixel as one sample and its segmentation as the cluster assignment.

**F-ARI.** The Foreground Adjusted Rand Index is a modification of the ARI score ignoring background pixels, which often occupy the majority of the image. We argue that both metrics are necessary to assess the segmentation quality of a video decomposition method; this metric is also used in [17, 43].

**MSE.** The mean squared error between pixels of the reconstructed \( \hat{x} \) and the ground truth frames \( x \).

### 4.3 Video Decomposition

We evaluate the models on a video decomposition task at different sequence lengths. As shown in Table 1 our model outperforms the baselines regardless of the presence of color information, which further reduces the error. We are at least 7% better than R-NEM on all metrics and at least 20% than IODINE on ARI and MSE. Since R-NEM cannot cope well with colored data or perspective of the scenes, it is only evaluated on the Bouncing Balls dataset (binary) producing high-error results in the first frames, a phenomenon not affecting our model. For both datasets IODINE’s results are computed independently on each frame of the longest sequence, by processing frames separately IODINE does not keep the same object-slot assignment, we chose to ignore it when computing the scores.

### 4.4 Generalization

We investigated how well our model adapts to a higher number of objects, evaluating its performance on the Bouncing Balls dataset (6 to 8 objects) and on the CLEVRER dataset (6 objects). Table 2 shows that our F-ARI and MSE scores are at least 50% better than those for R-NEM, and ARI scores are just marginally worse and only on the binary data. In comparison to IODINE we are at least 4% better across all metrics. For the Bouncing Balls dataset we have also investigated the impact of changing the total number of possible colors to 4 and 8. The former resulting in duplicate colors for different objects and the latter in unique colors for each object. The higher MSE scores for the 8 balls variant is due to the model not being able to reconstruct the unseen colors. Sample qualitative results are shown in Fig. 3 and 4, while more can be found in the supplementary material.
Figure 4: Qualitative Evaluation (CLEVRER). Our model can generalize to sequences with 6 objects. Furthermore, we demonstrate the ability to handle a dynamically changing number of objects, ranging from 4 in the beginning to 6 at the end.

Table 2: Generalization. At test time, we change the number of slots in the models from 5 to 9 for the Bouncing Balls test dataset (6-8 balls), and from 6 to 7 for the CLEVRER test dataset (6 objects).

| Bouncing Balls | ARI (↑)  | F-ARI (↑) | MSE (↓) |
|----------------|----------|-----------|---------|
| R-NEM          | 0.4484   | 0.6377    | 0.0328  |
| IODINE         | 0.0271   | 0.9969    | 0.0040  |
| SEQ-IODINE     | 0.0263   | 0.8874    | 0.0521  |
| Our            | 0.4453   | 0.9999    | 0.0008  |

| Color          | ARI (↑)  | F-ARI (↑) | MSE (↓) |
|----------------|----------|-----------|---------|
| IODINE (4)     | 0.4136   | 0.8211    | 0.0138  |
| IODINE (8)     | 0.2823   | 0.7197    | 0.0281  |
| SEQ-IODINE (4) | 0.2068   | 0.5854    | 0.0338  |
| SEQ-IODINE (8) | 0.1571   | 0.5231    | 0.0433  |
| Our (4)        | 0.4275   | 0.9998    | 0.0004  |
| Our (8)        | 0.4317   | 0.9999    | 0.0114  |

| CLEVRER | ARI (↑)  | F-ARI (↑) | MSE (↓) |
|---------|----------|-----------|---------|
| IODINE  | 0.2205   | 0.9305    | 0.0008  |
| SEQ-IODINE | 0.1482 | 0.8645    | 0.0012  |
| Our     | 0.2839   | 0.9355    | 0.0004  |

Table 3: Ablation Study. A 2D-LSTM extension of IODINE trained on sequences of 20 frames is unstable and its output segmentation lacks precision and consistency. Our efficient version of 2D-LSTM grid (Fig. 2a) and the conditional prior and generation increase both segmentation and reconstruction quality. Training this model on longer sequences of 40 frames we observe further improvement of the scores. Our full models including the entropy loss term (Eq.(7)) leads to the highest scores.

| Base | Grid | CP+G | Entropy | Length | ARI (↑)  | F-ARI (↑) | MSE (↓) |
|------|------|------|---------|--------|----------|-----------|---------|
| ✓    | ✓    | ✓    | ✓       | ✓      | ✓        | ✓        | ✓       |

4.5 Prediction

We compare the predictions of our model (Section 3.2.3) to those of R-NEM after 20 steps of inference on 10 predicted steps on the Bouncing Balls dataset (Fig. 5a). As we can see from the results our model is superior to R-NEM on a shorter sequences, however for the longer sequences we are outperforming R-NEM only on colored data. We also show the prediction errors on the CLEVRER dataset in Fig. 5b, which slowly decreases over time as expected.

4.6 Ablation

The quantitative results for the ablation study on the binary Bouncing Balls dataset are shown in Table 3. We investigate the effects of the efficient grid, conditional prior and generation, length of training sequences and entropy term on the performance of our model; all necessary and important.

Figure 5: Prediction. We plot the prediction errors for 3, 5, 7 and 10 frames after 20 inference steps.
5 Conclusion

We presented a novel unsupervised learning framework capable of precise scene decomposition and dynamics modeling in multi-object videos with complex appearance and motion. The proposed approach leverages temporal consistency between latent random variables expressed through a variational energy resulting in a robust and efficient inference model. These leads to the state-of-the-art in decomposition, segmentation and prediction tasks on several datasets, one of which collected by us. Notably, our model generalizes well to more populous scenes and has improved stability in scenes with missing color information due to the entropy term.

Acknowledgments and Disclosure of Funding

Supplemental Material

A Baselines

A.1 R-NEM

We use the R-NEM [43] authors’ original implementation and their publicly available models: https://github.com/sjoerdvansteenkiste/Relational-NEM.

A.2 IODINE

Our IODINE experiments are based on the following PyTorch implementation: https://github.com/MichaelKevinKelly/IODINE. We use the same parameters as in this code, with the exceptions of $\beta = 10$ (weight factor) and, for the Bouncing Balls experiments, $R = 6$ (refinement steps). The majority of the hyperparameters shared between our own model and IODINE are identical.

A.3 SEQ-IODINE

In order to test the sequential version of IODINE, we use the regularly trained IODINE model but change the number of refinement steps to the number of video frames during testing. During each refinement step, instead of computing the error between the reconstructed image and the ground truth image, we use the next video frame. Since the IODINE model was trained on $R = 6$ refinement steps, extending the number of refinement steps to the video length leads to exploding gradients. This effect is especially problematic in the binary Bouncing Balls dataset with 20, 30 and 40 frames per video, because the scores of the static model are already low. We deal with this issue by clamping with $\max = 10$ and $\min = -10$ the gradients and the $\delta$ refinement value in this experiment. SEQ-IODINE’s weak performance, especially w.r.t. the ARI, reflect the gradual divergence from the optimum as the number of frames increases.

B Datasets

Bouncing Balls. Bouncing Balls is a dataset provided by the authors of R-NEM [43]. We use the train and test splits of this dataset in two different versions: binary and color. For the color version, we randomly choose 4 colors for the 4-balls (sub-)dataset. For the 6-8 balls test data, we color them in 2 different ways: 4 colors (same as train) and 8 colors (4 from train, 4 new ones). Note that the former results in identical colors for multiple objects, while the latter guarantees unique colors for each object.

CLEVRER. The version of the CLEVRER dataset [49] used in this work was processed as follows:

- Train split, validation split and validation annotations were obtained from the official website: http://clevrer.csail.mit.edu/. We use the validation set as test set, because the test set does not contain annotations.
- For training, we use the original train split. Our minimal preprocessing consists of cropping the frames along the width axis by 40 pixels on both sides, followed by a uniform downscaling to 64x64 pixels. Since the length of each video is 128 frames and the maximum number of frames during training was 40, we split the videos into multiple sequences to obtain a larger number of training samples.
- For testing, we trim the videos to a subsequence containing at least 3 objects and object motion. We compute these subsequences by running the script (slice_videos_from_annotations.py in the attached code) from the folder with the validation split and validation annotations.
- The test set ground truth masks can be downloaded from here. The masks and the preprocessed test videos will be grouped into separate folders based on the number of objects in a video.

C Hyperparameters

Initialization. We initialize the parameters of the posterior $\lambda$ by sampling from $U(-0.5, 0.5)$. In all experiments, we use a latent dimensionality $\text{dim}(z) = 64$, such that $\text{dim}(\lambda) = 128$. Horizontal and vertical hidden states and cell states are of size 128, initialized with zeros. The variance of the likelihood is set to $\sigma = 0.3$ in all experiments.

Experiments on Bouncing Balls. For this experiment, we have explored several values of $R$ (refinement steps) and empirically found $R = 6$ to be optimal in terms of accuracy and efficiency. Refining the posterior more than 6 times does not lead to any substantial improvement, however, the time and memory consumption is significantly increased. For the 4-balls dataset, we use $K = 5$ slots for train and test. For our tests on 6-8 balls,

\footnote{Please note that clamping was done only when applied to binary Bouncing Balls for 20, 30 and 40 frames.}
we use $K = 9$ slots. This protocol is identical to the one used in R-NEM [43]. Furthermore, we set $\beta = 100.0$ and scale the KL term by $\psi = 10$. The weight of the entropy term is set to $\gamma = 0.1$ in the binary case. As expected, the effect of the entropy term is most pronounced with binary data, so we set $\gamma = 0$ in all experiments with RGB data.

**Experiments on CLEVRER.** We keep the default number of iterative refinements at $R = 5$, because we did not observe any substantial improvements from a further increase. We use $K = 6$ slots during training, $K = 6$ slot when testing on 3-5 objects and $K = 7$ slots when testing on 6 objects.

**D Training**

We use ADAM [27] for all experiments, with a learning rate of 0.0003 and default values for all remaining parameters. During training, we gradually increase the number of frames per video, as we have found this to make the optimisation more stable. We start with sequences of length 4 and train the model until we observe a stagnant loss or posterior collapse. At the beginning of training, the batch size is 32 and is gradually decreased negatively proportional to the number of frames in the video.

**E Infrastructure and Runtime**

We train our models on 8 GeForce GTX 1080 Ti GPUs, which takes approximately one day per model.

**F Discussion and Future work**

Introduction of a temporal component not only enables modelling of dynamics inside the amortized iterative inference framework but also improves the quality of the results overall. From our quantitative and qualitative comparisons with IODINE and SEQ-IODINE, we see that our model shows more accurate results on the decomposition task. We can detect new objects faster and are less sensitive to color, because our model can leverage the objects’ motion cues. The ability to work with complex colored data, a property inherited from IODINE, means that we significantly outperform R-NEM. However, R-NEM is a stronger model when it comes to prediction of longer sequences, owing to its ability to model the relations between the objects in the scene. Similar ideas were used in SQAIR [29] and GENESIS [10] by adding a relational RNN [39]. Integration of these concepts into our framework is a promising direction for future research. Another possible route is an application of our model to complex real-world scenarios. However, given that such datasets typically contain a much higher number of objects, as well as intricate interactions and spatially varying materials, we consider the resulting scalability questions as a separate line of research.

**G Additional Qualitative Results**

![Figure 6: Video decomposition using our model applied on Bouncing Balls dataset with 4 balls.](image1)

![Figure 7: Video decomposition using our model applied on Bouncing Balls dataset with 6-8 balls.](image2)
Figure 8: Prediction on Bouncing Balls (colored) dataset.

Figure 9: Prediction on CLEVRER dataset.

Figure 10: Qualitative results for Ours vs. IODINE vs. SEQ-IODINE decomposition experiment. (a) From the figure it is clear that our model can much sooner detect new objects emerging to the frame, while SEQ-IODINE struggles to properly reconstruct and decompose them. And IODINE doesn’t have any temporal consistence and reshuffles the slot order. (b) Here we can see that our model is much more stable with time and it does not fail to detect objects, unlike IODINE and SEQ-IODINE.
Figure 11: Disentanglement of the latent representations corresponding to distinct interpretable features. CLEVRER latent walks along three different dimensions: color, size and position. We chose a random frame and for each object’s representation in the scene dimensions were traversed independently.

H Disentanglement

We demonstrate that introducing a new temporal hidden state and an additional MLP in front of the spatial broadcast decoder has not impacted its ability to separate each object’s representations and disentangles them based on color, position, size and other features, similar to results shown in [17].
