Abstract

Spontaneous mediastinal hematoma is exceedingly rare. We described such a case of a 61-year-old male with a posterior mediastinal hematoma from ruptured small aneurysm, which was ascertained via contrast-enhanced computed tomography examination. Subsequent super-selective angiography of left gastric artery revealed a ruptured aneurysm with contrast medium leakage, feeding vessels respectively from caudal and cranial artery. The left gastric artery branch caudally feeding aneurysm was successfully occluded, while cranially feeding artery from the branch of left bronchial artery failed to embolize due to complex anatomic factor. Our management still yields to a satisfactory outcome.

Case Report

A 61-year-old man presented to the cardiovascular department with a 2-day history of fatigue, excessive sweat, mild chest and epigastric pain. His chest pain did not relieve with the position change. He had no significant past medical or surgical history, except for chronic bronchitis and bronchiectasis 20 years previously. The patient denied having sustained any trauma to his chest prior to admission. He was also not taking any anticoagulant agents and had no sign of disease causing bleeding tendency. On physical examination, his vitals were pulse 120 beats/min, blood pressure 96/66 mmHg, respiratory rate 16/min, and the oxygen saturation 96% on room air. Chest examination revealed crepitations in bilateral basal lung area. A complete blood cell count indicated an elevated white blood cell count of 16.15×10^9/L but mild decreased hemoglobin of 103 g/L. Coagulation screen was within normal limit. Non-enhanced chest computed tomography showed a large mixed-density posterior mediastinal mass extending from the level of gastric cardia to aortic arch together with bilateral pleural effusion, measuring 20.7×9.3×5.0 cm with corresponding mass effect shifting left atrium and esophagus. Cystic bronchiectasis was also seen in both lungs, predominantly in the left lower lobe (Figure 1). Because mediastinal hematoma was visible, contrast-enhanced CT was further required for the assessment of thoracic vessels. Subsequent CT scan revealed massive mediastinal hematoma and an aneurysm mainly originating from the branch of left gastric artery (Figure 2). On day two of admission, repeated blood test demonstrated a decreased hemoglobin value from 103 g/L to 86 g/L, suggesting active bleeding. The patient’s vital sign was stabilized with fluid challenge and transfusion, and was transferred to the angiographic room in an attempt to control active bleeding. Firstly, super-selective angiography of left gastric artery revealed an aneurysm measuring 10 mm in diameter located in the inferior-posterior mediastinum with contrast medium leakage, feeding vessels respectively from caudal and cranial artery (Figure 3). Transcatheter arterial embolization was performed via a coaxial catheter technique, and a long segment of the left gastric artery branch feeding aneurysm was successfully occluded with five micro-coils and gelatin sponge particles by an interventional radiologist. Then, cranial feeding artery of mediastinal aneurysm was completely searched and the branch of the left bronchial artery was suspected to be the culprit. Left bronchial artery originated from the concave side of proximal left subclavian artery and coursed tortuously. The embolization was cancelled because coaxial catheter failed to be introduced. After the procedure of transcatheter embolization, the patient immediately recovered from hemodynamic instability without any drop at his hemoglobin level on consecutive 5 days and was discharged home on the 7th day. At the 1-month follow-up period, contrast-enhanced CT showed decreased size of mediastinal hematoma measuring 18.1×7.4×3.6 cm. At 1-year telephone follow-up, he recovered to normal condition and refused any examination.

Discussion and Conclusions

Posterior mediastinal hematoma almost always follows chest trauma like vertebral body...
fractures. Invasive procedures to the neck and chest can induce the occurrence of mediastinal hematomas, such as central line placement, open-heart surgery, cardiac catheterization (in particular, associated with transradial approach), transbronchial biopsies, and thyroid surgery. Spontaneous mediastinal hematoma is defined as mediastinal hematoma occurring without apparent external cause. In those patients, underlying predisposing factors such as abnormal hemostasis, mediastinal/lower cervical neoplasms, and vasculopathies are frequently common. A sudden increase in intrathoracic pressure such as coughing, sneezing, or vomiting can cause mediastinal hematoma. Severe coughing seems to have been a major precipitating factor in the development of the hematoma in the reported literature. Based on the fact above, uncontrolled cough from bronchiectasis may facilitate mediastinal small aneurysm rupture in our patient. Mediastinal hematoma is a rare event with an indistinct clinical presentation.

![Figure 1. Chest computed tomography scan showed remarked cystic bronchiectasis in the lower lobe of left lung with mediastinal mass and bilateral pleural effusion.](image1)

The most common presenting symptoms among patients who are hemodynamically stable are shortness of breath and chest pain. Additional presenting symptoms may include respiratory distress, hypotension, tachycardia, chest wall ecchymosis, and dysphagia secondary to the compression of the esophagus by an expanding hematoma.

The available imaging modalities used for diagnosing mediastinal hematoma include sonography, chest radiography, chest CT and magnetic resonance imaging. Appropriate imaging examination and meticulous observation of key imaging features are important for determining the bleeding origin. Currently, chest CT scan is the most frequently used modality in evaluating those suspected patients with mediastinal hematoma because it can allow for a rapid and noninvasive evaluation of the mediastinum and adjacent structures. Contrast-enhanced CT angiography, allows better images with respect to the depiction of ectopic bronchial arteries and non-bronchial systemic collateral arteries. To our knowledge, mediastinal hematoma from ruptured aneurysm of the branch of left gastric artery is not documented in the literature. Given this patient’s history and findings on CT imaging, it is likely that his aneurysm occurrence was related to long-term bronchiectasis. As known, chronic infectious lung diseases including bronchiectasis frequently result in well-developed collateral circulation of bronchial and non-bronchial systemic arteries. The branch of left bronchial artery likely communicates the branch of left gastric artery resulting in the formation of aneurysm in this case. CT investigation plays an important role in establishing the diagnosis and guiding further treatment.

Mediastinal hematoma can be a threat to hemodynamic stability, not only as a source of blood loss, but also as a potential source of compression to vascular structures such as the heart and pulmonary arteries. Diligent monitoring of the patient’s vital signs and hemato logical indices were paramount. Once the patient’s hemoglobin continues to decrease, a prompt intervention must be initiated. Management of mediastinal hematoma centers on surgery and conservative management. It is treated conventionally by complete resection via open thoracotomy, but now minimal invasive port-access thoracoscopic is more popular. Hemodynamic control can also be accomplished via embolization after identifying the bleeding site through angiography. As benign clinical course and spontaneous resolution make conservative management feasible for those patients with asymptomatic hematoma, less-invasive embolization is more and more preferred in those patients with vascular lesions. In our patient, one side artery supplying aneurysm was embolized and yielded to a satisfactory outcome, while the branch of left bronchial artery failed to be embolized and remained untreated. According to our speculation, circular passage of aneurysm was cut off and the decrease of aneurysm pressure was not enough to facilitate blood extravasation.

In conclusion, our case is unique with respect to the origin of bleeding vessels. Collateral circulation of bronchial and non-bronchial systemic arteries is possibly responsible for the occurrence of mediastinal aneurysm and consequent bleeding. Transcatheter embolization is a feasible and effective treatment option under these circumstances.
