ABSTRACT

In this study, the flocculation properties of FucoPol, a bacterial extracellular polysaccharide, were investigated. FucoPol is a high molecular weight polymer and negatively charged due to the presence of glucuronic acid and the acyl groups succinyl and pyruvyl. High flocculation rate values (>70%) were achieved with a low biofloculant dosage of 1 mg/L for pH values in the range 3–5 and temperature within 15–20°C. The biofloculant was also shown to be stable after freezing/thawing and heating up to 100°C. Given the polymer’s anionic character, the size of flocs formed and their surface profile, bridging seems to be the main flocculation mechanism of FucoPol. This study demonstrated that FucoPol is a promising natural, biodegradable and biocompatible alternative to the currently used synthetic or inorganic hazardous products, with potential to be used as a novel flocculation agent in several applications, such as water treatment, food or mining. Further studies will involve evaluating the reduction of cation dosage on flocculation efficiency, as well as testing the applicability of FucoPol to flocculate different types of suspended solids, such as, for example, activated carbons, soil solids or yeast cells.

1. Introduction

Nowadays, flocculants are widely used in wastewater and drinking-water treatment, food and fermentation downstream processing, as well as in textile, pharmaceutical and cosmetic industries. They can be classified as inorganic flocculants (e.g. aluminum sulfate, polyaluminium chloride), organic synthetic flocculants (e.g. polyacrylamide derivatives, polyethyleneimine) and bioflocculants (e.g. chitosan, sodium alginate, microbial flocculants) [1]. Synthetic and inorganic flocculants are the most commonly used, due to their lower costs and high efficiency [2]. However, some of them pose health and/or environmental problems. Most of them are not
biodegradable. In the case of polyacrylamide-derived flocculants, for example, their acrylamide monomer is known to be highly toxic and carcinogenic [3]. Moreover, aluminum salts are known to cause Alzheimer’s disease [4]. Bioflocculants are macromolecules obtained from natural sources which have the ability to flocculate particles (suspended solids, cells, colloidal solids) out of solution [2]. These flocculants are emerging as attractive alternatives to the traditional flocculants, thanks to their biodegradable and usually safe nature.

Over the past few decades, many microorganisms, such as bacteria, algae and fungi, have been reported to produce polymers presenting flocculating capacity [1]. These macromolecules include proteins, glycopeptides and polysaccharides. Microbial biopolymer flocculants have the advantage of being produced economically at large scale, under controlled environmental conditions, while being usually easily recovered from the fermentation broth. Hence, these bi-friendly compounds deserve more and more interest.

Two mechanisms were proposed to describe the aggregation of particles by biopolymer flocculants, namely, polymer bridging and charge neutralization, which depend on the physical and chemical characteristics of the flocculant agent [5]. When a neutral flocculant is adopted or when the flocculant has the same charge as the particles, the polymer’s chains bring the particles closer together in order to form flocs. In this case, a cation is usually involved in view to reduce the effect of the charges and facilitates the adsorption of the particles by the bioflocculant. According to a charge neutralization mechanism, the biopolymer flocculant is expected to reduce the charge density of the particle surface and, with as end results, the formation of flocs by reduction of the coulombic repulsion forces between particles [5].

Microorganisms such as Rhodococcus erythropolis [6] and Bacillus subtilis [7] produce protein flocculants, whereas the bioflocculants produced by Bacillus licheniformis [8] and Halobacillus sp. [9] are composed of glycoproteins. However, the majority of bioflocculant-producing organisms, such as Bacillus sp., Aeromonas sp., Klebsiella sp. and Enterobacter sp., are known to produce polysaccharide flocculants [1,10]. Several bacteria of the Genus Enterobacter were reported to produce carbohydrate polymers with interesting flocculation rate. Yokoi et al. [11] reported the potential of a biopolymer produced by Enterobacter sp. BY-29 to flocculate, not only inorganic suspensions, such as kaolin and activated carbon, but also organic suspensions of cellulose and yeast. Lu et al. [12] reported that the polysaccharide produced by E. aerogenes W-23 was able to flocculate a trona suspension with higher efficiency than conventional chemical flocculants. The extracellular polysaccharide synthesized by the bacterium Enterobacter A47, named FucoPol, was also reported to have flocculating capacity [13].

In this study, the flocculating capacity of FucoPol was assessed. Kaolin clay, a widely used model suspension to study the flocculation properties of flocculant materials, was used due to its stability and well defined surface properties, which lead to a better understanding of the flocculation process. The factors affecting the flocculating rate of the biopolymer (dosage, presence of different cations, dosage of cations, kaolin suspension concentration, pH and temperature) and the flocculation mechanism of FucoPol were investigated. Moreover, the cultivation broth, as well as the cell-free supernatant containing the biopolymer, were also tested for their flocculating activity.

2. Materials and methods

2.1. Bioflocculant production and characterization

The bacterium Enterobacter A47 was cultivated in a 2 L bioreactor (BioStat B-plus, Sartorius, Germany) using Medium E* supplemented with glycerol (40 g/L) [14]. The bioreactor was operated as described by Torres et al. [15]. The bioflocculant, FucoPol, was extracted from the cultivation broth as described by Ferreira et al. [16]. The apparent viscosity of the broth was measured as described by Freitas et al. [13]. The purified bioflocculant was characterized in terms of sugar monomers and acyl groups composition, total inorganic and protein contents, average molecular weight and polydispersity index, as described by Torres et al. [15]. The chemical structure of purified bioflocculant FucoPol was assessed by Fourier transform infrared spectroscopy (FT-IR) (Nicolet 6700 FT-IR, Thermo Electron Corporation, Waltham, MC, USA) with a diamond crystal attenuated total reflectance (ATR) accessory, over a wavenumber range of 525–4500 cm⁻¹.

2.2. Flocculation rate tests

The flocculation rate (FR) was measured using kaolin clay (Ref. 60609, Sigma-Aldrich, Germany) as the test solids suspension. The zeta potential of kaolin clay suspension used in this study was −24.8 mV. In brief, 4.9 mL of a CaCl₂ aqueous solution (249 mmol Ca²⁺ per litre) and 0.1 mL of the flocculating agent in aqueous solution were added into 45 mL of kaolin suspension (5 g/L, w/v) in Falcon™ conical tubes (30 × 115 mm). The mixtures were vigorously shaken for 20 s and allowed to stand for 5 min at room
temperature. Afterwards, one millilitre was removed from the upper layer of the suspension and the optical density was measured at 550 nm \( (\text{OD}_{550}) \). A blank sample was prepared by replacing the flocculating agent by the same volume of deionized water \( (\text{OD}_{550, \text{blank}}) \). The FR (%) was calculated according to the following equation:

\[
\text{FR} \, (\%) = \frac{\text{OD}_{550, \text{blank}} - \text{OD}_{550}}{\text{OD}_{550, \text{blank}}} \times 100
\]

The impact of various parameters on Fucopol’s flocculation rate was studied, namely, bioflocculant concentration (0.1–5.0 mg/L), suspended solids content (1–10 g/L), flocculation time (0–30 minutes), pH (3.4–11.6), temperature (5–60°C) and type of cation (NaCl, KCl, CaCl₂, MgCl₂, FeCl₂ and FeCl₃). The thermal stability of Fucopol was also examined by measuring the FR after subjecting a Fucopol solution (1 mg/L) to one of the following thermal treatments: (1) overnight freezing at −80°C, followed by thawing at room temperature; (2) heating at 80°C or 100°C for 2 h; (3) autoclaving at 121°C, 1 bar, for 20 min. All experiments were conducted with 5 replicates.

The flocculation rate of Enterobacter A47 culture broth and cell-free supernatant were evaluated throughout the cultivation run. Culture broth samples were diluted (1:10, v/v) with deionized water and centrifuged (10956 × g, 10 min) to obtain the cell-free supernatant samples. For determination of the flocculating activity, 0.1 mL samples (broth diluted 1:10 (v/v) and the corresponding cell-free supernatant) were added to the kaolin suspension and the FR was determined as described above. The measurements were performed at a temperature of 20°C.

### 2.3. Flocculation mechanism

Scanning electron microscope was used to observe the surface morphology of Fucopol, as well as the kaolin clay particles and the kaolin clay particles flocculated in the presence of Fucopol. Both type of particles were obtained after centrifuging the suspensions (3,500 × g, 5 min). The samples were dried freeze and their morphology was assessed through scanning electron microscopy in a Carl Zeiss AURIGA Crossbeam SEM-FIB microscope.

Two different methods, namely transmission optical microscopy and dynamic light scattering (DLS), were used to determine the particle size distribution of the kaolin suspension and the kaolin suspension flocculated with Fucopol. For the transmission optical microscopy analysis, the suspensions (20 µL) were spread on microscopy glass plates and observed with an Olympus Provis microscope, at magnification from 2.5 to 20×, at room temperature. Images were acquired with a Visicam 5.0 VWR. The micrographs, recorded under a bmp format, were calibrated with a certified reticle. DLS analysis was performed at 30°C using a Photocor equipment (helium–neon laser, 633 nm, 20 mW; 90° angle) and a BI9000 Brookhaven autocorrelator. Analysis were realized using two aliquot samples and performing at least three runs per sample for 1 min. DLS raw data were analysed with Dynals Software (SoftScientific, Israel).

### 3. Results and discussion

#### 3.1. Bioflocculant characterization

The bioflocculant used in this study, the extracellular polysaccharide Fucopol, was composed of fucose (35% mol), glucose (31% mol), galactose (24% mol) and glucuronic acid (10% mol). The acyl group substituents accounted for 12 wt% of the polymer’s mass and comprised pyruvyl, acetyl and succinyl residues. Total protein and inorganic salts contents of 11 wt% and 7 wt%, respectively, were detected. The polymer had an average molecular weight of 4.4 × 10⁶ Da and a polydispersity index of 1.9. These Fucopol features, i.e. a high molecular weight macromolecule containing several anionic residues (glucuronic acid monomers and the acyl substituents pyruvyl and succinyl), should support a bioflocculant property [1]. Having a high molecular weight and a high content of hydroxyl and carboxyl groups, namely, uronic acids, are characteristics known to favour the flocculation mechanism [1]. The presence of carboxyl groups, in particular, would allow the molecular chain to stretch as a means of reducing intra- and interchain electrostatic repulsion, thus giving rise to a conformation more adapted to promote a multi binding attachment to the kaolin particles [17,18].

The bioflocculant was characterized by FTIR spectroscopy (The FTIR spectrum is shown in supplementary material Figure S1). The spectrum showed a broad and intense band at 3327 cm⁻¹ characteristic of the stretching vibrations of the hydroxyl groups (O–H). This band overlaps with the peak located at 2926 cm⁻¹, which can be assigned to the stretching vibration of the C–H of the CH₂ groups. The peak at 1722 is due to the C=O stretching of carbonyl moieties present in the acyl substituents. The absorption peak observed at 1257 cm⁻¹ is characteristic of the C–O–C vibration of acyls. The band appearing at 1601 cm⁻¹ and the absorption region from 1300 to 1450 cm⁻¹ can be attributed to the asymmetric and symmetric stretching of carboxylates, which are present in the glucuronic acid. The strong adsorption peak at 1016 cm⁻¹ is characteristic of skeletal C–O and C–C vibrations of the glycosidic bonds and pyranoid
ring [13]. FTIR analysis supported that the bioflocculant is a carbohydrate containing acyl groups.

3.2. Flocculation of kaolin clay suspension with FucoPol

The flocculating capacity of FucoPol was evaluated by measuring the FR of a kaolin suspension (5 g/L, w/v) in the presence of 1.0 mg/L of the polymer. In order to assess the coagulation kinetics and define the optimum flocculation time, samples of kaolin clay suspension (blank) and of kaolin clay in the presence of FucoPol were prepared and allowed to stand for 30 min (Figure 1). Aliquots were sampled periodically from the upper layer of the test tubes and their optical density (OD$_{550}$) was measured for FR determination. As shown in Figure 2, after five minutes settling, the decrease in the optical density of the suspension containing FucoPol was considerably lower (0.33 ± 0.02) than that of the blank (1.52 ± 0.06), thus corresponding to an FR of 75 ± 9.3%. Afterwards, the optical density of the suspension containing FucoPol remained practically unchanged (0.21–0.27), while a gradual decrease was noticed for the blank, reaching a value of 0.35 ± 0.03 at 30 min. Accordingly, the FR decreased from 62 ± 8.9%, for a settling time of 10 min, to 34 ± 12.4% after 30 minutes. Due to the difference in kinetics evolution between the optical densities of the flocculated samples and the blank, a standard settling time of 5 min was selected for further testing FucoPol flocculation rate.

Figure 1. The formation of kaolin particles flocs by the function of FucoPol in presence of CaCl$_2$ after 5 minutes settling.

Figure 2. Optical density (measured at 550 nm, OD$_{550}$) of the upper layer of kaolin clay suspension (□) and kaolin clay suspension in the presence of FucoPol at a concentration of 1 mg/L (○), for different settling times, and the corresponding FR values (●).

3.3. Flocculation performance of FucoPol

3.3.1. Effect of bioflocculant dosage

Figure 3(a) presents the influence of bioflocculant dosage (tested FucoPol concentrations ranged between 0.1 and 5.0 mg/L) on the flocculation of kaolin particles. The flocculation rate increased asymptotically as a function of the biopolymer concentration within the concentration range of 0.1 to 1.0 mg/L, to reach a maximum of 74–76 ± 8.3%. Further increasing the bioflocculant dosage to 2 and 5 mg/L was not translated into any further improvement of the FR (Figure 3(a)). This dose-effect relationship can be explained by the need to have enough bioflocculant molecules in the mixture to coat the suspended kaolin clay particles and trigger the particles’ flocculation [1]. However, excessive bioflocculant dosages may lead to restabilization and change of charge of the colloid solution and reduction of the FR [5]. In fact, a lower FR (28%) was reported for the flocculation of kaolin clay particles with a FucoPol concentration of 100 mg/L, under similar test conditions [13]. A similar trend was reported by Aljuboori et al. [5] for the flocculation of kaolin particles by addition of the

Figure 3. Effect of bioflocculant dosage (a) and suspended solids content (b) on the flocculation rate of kaolin clay suspensions using FucoPol.
bioflocculant IH-7 produced by *Aspergillus flavus*, in which reduced FR values were caused by excessive bioflocculant dosage.

The FR values obtained for FucoPol dosages between 1.0 and 5.0 mg/L (74–76 ± 8.3%) are within the range of values reported by Subramanian et al. [19] for several microorganisms (68–86%) for bioflocculant dosages between 0.5 and 5.0 g/L. Considering these results, a FucoPol concentration of 1.0 mg/L was selected as the optimal dosage for the subsequent flocculation capacity tests.

### 3.3.2. Effect of suspended solids content

The effect of the suspended solids content was evaluated by testing the flocculation of different kaolin suspensions (between 1 and 10 g/L) in the presence of FucoPol at a concentration of 1.0 mg/L (Figure 3(b)). The maximum FR value (74 ± 7.3%) was reached with 5 g/L kaolin clay suspension, a concentration commonly used in flocculation activity studies [10]. Low suspended solids contents (kaolin contents of 1 and 3 g/L) led to low flocculation efficiency (FR = 30 and 70%, respectively), which might have been due to an insufficient number of kaolin particles available to form flocs. Above a concentration of 7 g/L of solids content, it is worth to notice that the FR also decreased (67–54 ± 6.2%). This observation therefore supports the hypothesis that bioflocculation efficiency is mainly affected by the number of bioflocculant molecules available to coat the kaolin particles and bring them together to form flocs. It can also be anticipated that the kaolin particles concentration in the suspension may also affect interparticle interaction, with a higher particle concentration being less favourable to promote floc formation due to mutual repulsive forces between the kaolin particles. A similar behaviour was reported for the flocculation of a synthetic clay suspension by the polysaccharide produced by *Bacillus mojavensis* strain 32A [20]. The flocculation efficiency was high (FR = 90%) for clay dosages of 1.25–5 g/L, decreasing to below 70% as the clay concentration was increased above that value. Also, for the bioflocculant produced by *A. flavus*, constant FR values (>95%) for kaolin contents in the range 0.5–8.0 g/L were reported by Aljuboori et al. [5]. For higher kaolin contents there was a slight decrease of the FR to 86%.

### 3.3.3. Effect of pH

As shown in Figure 4(a), the flocculation efficiency of FucoPol was affected by the pH value of the suspension. Similar FR (70–74%) were achieved for pH values between 3.4 and 5.4. These results suggest that FucoPol might be a bioflocculant suitable for use in acidic environments, such as wastewater treatment, food and mining industries. For pH ≥ 7.0, the FR gradually decreased to values below 60% (Figure 4(a)). This result is probably due to the evolution of ionization of FucoPol as a function of the pH value, which is known to affect the flocculation ability of the bioflocculants [21]. At more alkaline pH values, we should have more negative charges on FucoPol, as well as on kaolin, therefore promoting electric repulsion between the bioflocculant and kaolin particles.

Although some pH-resistant bioflocculants have been reported, such as the one produced by *Enterobacter* sp. ETH-2 with a high FR (>90%) in a pH range of 3–9 [22], most of the other flocculation agents are strongly affected by the pH value of the media. The pH dependence of FucoPol flocculation activity was similar to that of the polysaccharide secreted by *Achromobacter xylosidans* strain TERI L1 that was effective for flocculation of a kaolin clay suspension over a weakly acidic pH range (5.5–7.5) [23]. Aljuboori et al. [5] also reported the stability of the bioflocculant IH-7 at a pH range of 4–8. The bioflocculant produced by *Kelbsiella sp.* ZZ-3 also presented high FR values (>90%) between pH 3 and 7 that decreased (61–79%) for higher pH values [24]. These variations in the response of these bioflocculants to the pH value should be linked to the macromolecular features, such as their mean composition, monomer distribution and tertiary structure.

### 3.3.4. Effect of temperature

The FR of FucoPol was also influenced by the temperature. The highest FR values were noticed for temperatures between 15°C and 20°C (Figure 4(b)). Outside that range, either for lower (5°C) or higher temperatures (30–60°C), the FR values gradually decreased. If an increase in temperature should promote movement and collision of the suspended particles, and consequently the formation of flocs, variation in solvation and ionization level with temperature cannot be ruled out. For example, Pan et al. [21] reported the formation of smaller size flocs, with high hydrating capacity, at higher temperatures with a corresponding

![Figure 4](image-url)
decrease in the flocculation efficiency. Although some authors have reported broad thermal stability of their biofloculants, such as, for example, the biofloculant produced by B. subtilis DYU1 that maintained a FR above 80% for temperatures up to 100°C [18], in most of the cases, the flocculation ability of biopolymers is influenced by the temperature.

3.3.5. Thermal stability of the biofloculant
The thermal stability of the biofloculant was evaluated by submitting FucoPol solutions to different thermal treatments: (1) freezing at −80°C for 12 h, followed by thawing at room temperature; (2) heating at 80°C and 100°C for 2 h; (3) autoclaving at 121°C, 1 bar, for 20 min. Each solution was then used to flocculate kaolin clay suspensions (5 g/L).

Freezing/thawing did not significantly affect the flocculation capability of the biopolymer. After being submitted to that treatment, the biopolymer presented a FR of 72 ± 4.7% close to the value obtained for the untreated FucoPol solution (74 ± 7.3%). Similarly, heating the biopolymer’s solution at 80°C or 100°C had no significant impact on FucoPol’s flocculation efficiency, as shown by the high FR values obtained (71 ± 4.3% and 71 ± 3.4%, respectively).

These results demonstrate the thermal stability of FucoPol to temperatures up to 100°C. Generally, biofloculants composed mainly of carbohydrates have higher thermal stability, compared to biopolymers made from a peptide backbone that are more susceptible to heat. For example, the polysaccharide biofloculants synthesized by Enterobacter sp. ETH-2 [22], B. velezensis 40B [25] and Aeromonas sp. [26] were stable after treatments at temperatures up to 100°C, keeping their flocculation efficiency over 80%. In contrast, the biofloculant produced by B. subtilis DYU1 [18], mainly composed of polyglutamic acid, had reduced FR after treatment at 60°C and was completely inactivated when heated at 120°C.

However, upon autoclaving, FucoPol apparently loss its flocculating efficiency, as shown by the considerably lower FR value obtained (22 ± 6.2%). This thermal behaviour might be indicative of an alteration in the conformation of the polysaccharide chain or even a degradation of the biofloculant [24]. The FR of the biofloculant produced by Klebsiella sp. ZZ-3 has also shown a decrease of the FR value from 93% to 53.5% after being subjected to similar conditions (115°C, for 20 min) [24].

3.3.6. Effect of different cations
The effect of different cations on the flocculation rate of FucoPol was evaluated by using several chloride salts (NaCl, KCl, MgCl₂, FeCl₂ and FeCl₃) instead of CaCl₂ in the FR measurement tests. Lower FR values (<60%) were obtained in the presence of any of the tested cations, comparing to CaCl₂ (74 ± 7.3%) (Figure 5). Comparable FR values were reached for Na⁺ (49 ± 9.6%), K⁺ (53 ± 9.1%) and Fe²⁺ (51 ± 6.8%). On the other hand, the flocculation efficiency of FucoPol was strongly reduced in the presence of Mg²⁺ and Fe³⁺ (FR < 30%). Similar results were reported for the biofloculant produced by the consortium of Halomonas sp. and Micrococcus sp. [27]. The authors disclosed that the highest FR value was obtained for Ca²⁺ (72%), being reduced in the presence of monovalent (Li⁺, Na⁺ and K⁺) and other divalent (Mg²⁺, Mn²⁺ and Ba²⁺) cations. Also, the flocculation capacity of the biofloculants produced by several species of the Genera Bacillus, Pseudomonas, Seratia and Yersinia was improved by the presence of CaCl₂ [10]. Other cations, such Li⁺, Na⁺, K⁺, Mg²⁺, Al³⁺ and Fe³⁺, have also been tested in the presence of other biofloculants [5,27] and, in the most cases, the FR was influenced by the type of cation used. For example, the presence of Fe³⁺ led to a 40% decrease of the FR for the polysaccharide secreted by Klebsiella sp. ZZ-3 [24], while that of the biofloculant produced by Enterobacter sp. ETH-2 was completely lost [22]. The loss or reduction of the flocculation activity in the presence of Fe³⁺ has been assigned to the higher charge neutralization efficiency of kaolin particles by the cation [24].

3.4. Flocculation of kaolin clay suspension with culture broth and cell-free supernatant
The flocculation rate of Enterobacter A47 culture broth and its cell-free supernatant were also evaluated for samples collected at different cultivation times (Table 1). This approach would be of interest since for many applications (e.g. wastewater treatment) there is no need for a biofloculant with a high purity degree. Hence, the direct use of Enterobacter A47 culture broth or even its cell-free supernatant as bioflocculating agents would result in a less
Table 1. Flocculation rate of Enterobacter A47 cultivation broth and cell-free supernatant samples collected from the bioreactor during production of FucoPol.

| Cultivation time (h) | Fucopol (g/L) | Flocculant dosage (mg/L) | FR (%) | Broth | Supernatant |
|----------------------|---------------|--------------------------|--------|-------|-------------|
| 0                    | 0.16          | 0.03                     | 0      | 0     | 0           |
| 24                   | 0.72          | 0.14                     | 0      | 0     | 0           |
| 48                   | 2.83          | 0.57                     | 24 ± 5.1 | 59 ± 8.0 |
| 72                   | 5.00          | 1.00                     | 40 ± 5.2 | 65 ± 7.3 |
| 96                   | 6.20          | 1.24                     | 43 ± 4.4 | 76 ± 8.1 |

expensive product application since the procedures for polymer purification would not be necessary.

Due to the high viscosity developed by the broth during cultivation (an apparent viscosity of 910 mPa.s was reached after 96 h of cultivation, measured at 0.82 s⁻¹), the samples had to be diluted for cell removal by centrifugation. In view of this, all samples suffered the same dilution (1:10, v/v), so the broth samples and the corresponding cell-free supernatant samples would be tested at the same bioflocculant dosage. The results show that both the broth and the supernatant samples demonstrated to possess flocculating activity that increased along the cultivation time (Table 1). Up to 24 h of cultivation, no flocculating capacity was detected, which demonstrates that the medium had no flocculating capacity and the observed flocculation ability derived from the bacterial products. At 48 h of cultivation, FR values of 24 ± 5.1% and 59 ± 8.0% were detected for the broth and the supernatant samples, respectively. The flocculating activity of both type of samples further increased along the cultivation run, reaching maximum values of 43 ± 4.4% and 76 ± 8.1% respectively, at the end of the experiment (Table 1). The observed increase of the FR was concomitant with the polymer’s synthesis and, thus, with the bioflocculant’s dosage.

Interestingly, for all cultivation times, the supernatant samples disclosed considerably higher FR values than the broth samples, despite having the same bioflocculant dosage. Actually, the FR of the cell-free supernatant samples was 40–61% higher than the corresponding broth samples. These results suggest that, for the same total Fucopol concentration in both types of samples, the biopolymer’s flocculating ability is significantly affected by the medium, namely the cell content. Due to its biological function, it can be anticipated that Fucopol might remain loosely attached to the cell surface after secretion, thus decreasing its availability to interact with the kaolin particles [28]. The maximum FR obtained for Enterobacter A47 cell-free supernatant, 59–65%, is similar to the values (63–76%) reported for several studies in which cell-free supernatant samples of several bacteria (e.g. Achromobacter xylosidans strain TERI L1 [23], Halobacillus sp. Mvuyo [9], and the consortium of Halomonas sp. Okoh and Micrococcus sp. Leo [27]) were tested as flocculating agents. Higher FR values (>80%) were also reported for the cell-free supernatant of some other microbial bioflocculant producers, including B. subtilis [7,18], B. mucilaginosus MBFA9 [17] and Enterobacter sp. ETH-2 [22]. Nonetheless, in most of those reports, considerably higher supernatant dosages (10–100 mL/L) were used for testing the flocculation rate, compared to a dosage of 2 mL/L used in the present study.

3.5. Flocculation mechanism of Fucopol

3.5.1. Surface morphology of Fucopol and kaolin flocs

The surface morphology of dried Fucopol, kaolin clay particles and kaolin clay particles flocculated in the presence of Fucopol was observed under scanning electron microscopy (SEM) (Figure 6). As shown in Figure 6(a), Fucopol exhibits a fibrous structure with interstitial spaces between the ribbon-like fibres network. Figures 6(b,c) show the morphology of the kaolin clay particles and the kaolin clay particles flocculated with Fucopol, respectively. It can be observed that the kaolin clay particles were small and homogeneously dispersed, while in the presence of Fucopol, considerably larger flocs were formed. Apparently, the scattered kaolin clay small particles (Figure 6(b)) were connected together into large particles in the presence of Fucopol (Figure 6(c)), therefore highlighting the flocculating performance of the biopolymer for kaolin clay particles.

Figure 6. Scanning electron micrograph of (A) purified Fucopol, (B) kaolin clay particles and (C) kaolin clay particles flocculated with purified Fucopol (1 mg/L).
The formation of multiaggregates in the presence of FucoPol was also clearly demonstrated by the particle size analysis of the suspensions analyzed by optical microscopy and DLS. Before coagulation, kaolin particles have a mean size around 10 µm (mean Id in DLS) but characterized by a larger polydispersity index, with particles in a size range from 5 to 20 µm (in some cases up to 50 µm). After FucoPol addition, aggregates are mostly found with a particle size range typically above 20 µm up to 75 µm (the particle size distribution is shown in supplementary material, Figure S2).

3.5.2. Flocculation mechanism
Kaolin particles are negatively charged [5,22]. Since FucoPol is an anionic polysaccharide due to the presence of negatively charged carboxyl groups (i.e. glucuronic acid, pyruvic acid and succinic acid), charge neutralization could not be the main mechanism to describe kaolin particles flocculation by FucoPol. For flocc formation, the electrostatic repulsion between the negatively charged kaolin particles must be reduced, which was likely achieved by the presence of Ca\(^{2+}\). Accordingly, the Ca\(^{2+}\)-kaolin complexes would interact more easily with the negatively charged carboxyl groups of FucoPol. Due to its high average molecular weight (4.4 × 10^6 Da), the biofloculant should be able to bridge particles, leading to the formation of three-dimensional flocs able to settle faster than the kaolin particles alone [18].

4. Conclusions
FucoPol, an exopolysaccharide produced by Enterobacter A47, demonstrated to efficiently flocculate kaolin suspension. Its high molecular weight, combined with the presence of numerous negative charged residues, rendered FucoPol a good flocculation performance at low dosages. High flocculation effectiveness was demonstrated for wide ranges of pH and temperatures, and FucoPol was shown to be thermally stable, suggesting its applicability in both cold and hot conditions. Polymer bridging was probably the main mechanism of flocculation considering the nature of the bioflocculant. This study revealed that FucoPol has good potential for colloid aggregation in several applications, such as water treatment, food and mining industries, able to compete with other natural and/or synthetic flocculants.
