THE NATURE OF THE ACTIVITY IN HICKSON COMPACT GROUPS OF GALAXIES

ABSTRACT

We present the results of the spectral classification of the 82 brightest galaxies in a sample of 17 compact groups. We verify that the active galactic nuclei (AGNs) are preferentially located in the most early-type and luminous galaxies of the groups, as is usually observed in the field. But these AGNs also appear to be systematically concentrated toward the central parts of the groups. Our observations suggest a correlation between activity types, morphologies, and densities of galaxies in the compact groups. This is consistent with a scenario in which galaxies of compact groups evolve by interacting with their environment and are currently in a quiet phase of their activity.

Subject headings: galaxies: active — galaxies: clusters: general — galaxies: interactions

1. INTRODUCTION

One of the important aspects of the study of the Hickson compact groups of galaxies (HCGs; Hickson 1982) lies in the attractive possibility of assessing the effects of strong interactions on the morphology and stellar content of galaxies (Hickson et al. 1992). The available data on the HCGs, however, seem to present many contradictions with a fast-merging evolution scenario, suggesting that we still do not fully understand the nature of these systems. To shed light on this problem, a new spectroscopic survey of faint galaxies in the regions of HCGs was recently undertaken by de Carvalho et al. (1997; see also Ribeiro et al. 1997) to determine the kinematical structure of the groups. These studies show that HCGs exhibit a variety of dynamical configurations, as opposed to the previous view of them as isolated and high-density structures.

Spectroscopic observations of galaxies around HCGs not only allow us to establish how isolated these structures are from other structures, but they also yield valuable information on the nature of the activity of the individual groups. Previous studies on the activity of the galaxies in compact groups have led to contradictory conclusions. Recently, for example, Sulenti & Rabaça (1993) and Vegnugopal (1995) have contested the claim by Hickson et al. (1989) that the far-infrared emission is enhanced in compact groups. Radio observations (Monen 1992, 1995) and optical spectroscopy and imaging (Rubin, Ford, & Hunter 1991) all suggest that tidal interactions and mergers between compact group galaxies did happen in the past. However, many galaxies in the groups seem to be normal, and it is not clear which phenomenon—either starburst or active galactic nucleus (AGN)—is the main source of activity observed in the groups. One extreme example of activities encountered in a compact group is HCG 16, which includes one Seyfert 2 galaxy, two luminous low-ionization nuclear emission-line regions (LINERs), and three starburst galaxies (Ribeiro et al. 1996). But in a sample of 17 groups, HCG 16 is the only one of its kind, which suggests that, in general, the activity in the groups is not prominent.

In this contribution we present the results of our classification of the activity types of a sample of luminous galaxies from 17 HCGs. We show that a significant fraction of these galaxies display AGN activity. Moreover, 50% of the AGN population in the groups as studied here are “low-luminosity” AGNs (LLAGNs)—that is, faint AGNs, either Seyfert 2 or LINER, which are hidden behind the strong stellar continuum of their host galaxy. We also show that the AGN population always appears segregated toward the compact cores (which generally encompass most of Hickson’s original compact groups; Ribeiro et al. 1997), whereas starburst galaxies tend to be distributed in their external parts.

The organization of the paper is as follows. In § 2 we define our sample of compact group galaxies and explain the criteria that we used in our classification. We present the characteristics of the LLAGNs in our sample and show the results of template subtraction, which is an essential part of the classification scheme. The results of our classification of all the emission-line galaxies following two diagnostic diagrams of line ratios are also presented in this section. In § 2.1 we present a brief discussion of the low-luminosity nature of the LLAGNs. In § 3 we discuss the spatial and morphological distribution of the active galaxies in the compact groups. We conclude in § 4 with a brief digression on the significance of our findings for the understanding of the nature of compact groups.

2. SPECTRAL CLASSIFICATION OF THE AGN CANDIDATES

The spectra presented in this paper are part of a sample of 316 galaxies in the regions of 17 HCGs that were observed by de Carvalho et al. (1997). The spectra were taken at the 4 m CTIO telescope, using the ARGUS fiber-fed spectrograph. The details of the instrumental setup and data reduction are discussed by de Carvalho et al. (1997). In this sample 82 galaxies (of which only 67 are kinematically assigned to the groups; see de Carvalho et al. 1997) have spectra with sufficiently high S/N to allow a proper classification of the activity type. Of these galaxies, 28 (34%) present only absorption lines, and 54 (66%) present both emission and absorption lines. In this article the non-emission-line galaxies are considered nonactive. A complete analysis of the absorption features in these galaxies will be published elsewhere (Coziol et al. 1997b). This paper is dedicated to the classification of the emission-line galaxies.

Luminous emission-line galaxies are usually easy to identify and classify. These galaxies are either starburst galaxies or AGNs. For many galaxies in our sample, however, the usual classification criteria cannot be applied directly, since they do not show any emission lines (i.e., within the limits of our observations), with the exception of the $[\text{N} \text{II}] \lambda 6584$ line. Figure 1 shows the spectra for these galaxies. The great similarity of the spectra suggests either that all of these galaxies are of similar morphological type, or that they are dominated by the same stellar populations. The trace of ionized gas in early-type spirals and ellipticals was already observed before, and it is generally suggested that a mild Seyfert or LINER, that is, a low-luminosity AGN, could reside in the nuclei of all these galaxies (see Filippenko & Sargent 1985; Phillips et al. 1986; hereafter PJDSB). Given the similarity of the phenomenon observed here, we will provisionally call the subsample of the galaxies displayed in Figure 1 the LLAGN candidates. The basic characteristics of the LLAGN candidates are presented in Table 1. The numbers in columns (1) and (2) follow the numbering used in de Carvalho et al. (1997), and the letters in column (3) correspond to the galaxies in the Hickson (1982) list. Redshifts determined by de Carvalho et al. (1997) are listed in column (4). The $B$ luminosities, as taken from Hickson, Kindl, & Auman (1989a) and Hickson et al. (1989), are listed in column (5). The absolute magnitudes, presented in column (6), were determined assuming $H_0 = 75$ km s$^{-1}$ Mpc$^{-1}$. In column (7) we also give the morphologies of the galaxies as reported by Mendes de Oliveira & Hickson (1994).

For the LLAGN candidates, the presence of an intermediate-age stellar population introduces strong Balmer absorption lines that interfere with the observation of faint ionized regions. The problem of detecting and measuring weak emission lines atop a strong stellar continuum has already been tackled by several groups of investigators in the past. Subtraction of a template galaxy spectrum that has no comparable emission has proved to be an effective technique. For our analysis we have taken advantage of having at hand a significant number of absorption-line galaxies, all observed under the same instrumental conditions, in order to build such a template. The spectral characteristics of the galaxies used as templates are remarkably similar to those of the LLAGN candidates. On average, the difference between the velocity dispersion of the absorption lines of our template galaxies and those of the LLAGN candidates is approximately 2, which is smaller than our resolution (~6 Å). Figure 2 shows the red part of the spectra of the LLAGN candidates after template subtraction. Note the high $[\text{N} \text{II}] \lambda 6584/H\alpha$ ratios typical of AGNs.

The classification of the activity type of all of the 54 emission-line galaxies in our sample was determined after subtraction of a galaxy template. The emission lines were measured by fitting Gaussian profiles. Our classification is based on the characteristic line ratios shown by galaxies of different activity classes (Baldwin, Phillips, & Terlevich...
1981; Veilleux & Osterbrock 1987). The emission-line galaxies in our sample were separated into three groups: starburst galaxies, AGNs, and LLAGNs.

The first diagnostic diagram, presented in Figure 3, is the diagram of [N II] λ6584/Hα versus [O III] λ5007/Hβ (Baldwin et al. 1981; Veilleux & Osterbrock 1987). The distinction between AGNs and starburst galaxies is based upon the empirical separation proposed by Veilleux & Osterbrock (1987). The separation between LINERs and Seyfert type 2 galaxies corresponds to log([O III] λ5007/Hβ) ≤ 0.4, as proposed by Coziol (1996). The same criterion is used to distinguish between low-excitation starburst-

![Fig. 2.—Spectra of the LLAGN candidates after subtraction of a template galaxy. The galaxies are shown in the same order as in Fig. 1. The ratios [N II] λ6584/Hα are high, and [O I] λ6300 is detected in almost all of the galaxies.](image-url)
nucleus galaxies (SBNGs) and the high-excitation H II galaxies. This diagnostic diagram confirms the AGN nature of all of our LLAGN candidates. It also indicates that the majority of these galaxies are LINER galaxies.

To double-check our classification, we also examined the ratio [O I] 6300/Hα. As was shown by Baldwin et al. (1981), the presence and strength of [O I] 6300 are important factors in distinguishing between starburst galaxies and AGNs. This is because this line is produced only in regions of partial ionization, which are much more extended in AGNs than in normal H II regions. For this reason the [O I] line is rarely observed and is always weaker in starburst galaxies than in AGNs. In our sample the [O I] line is detected in 61% of the starburst galaxies, 88% of the LLAGNs, and 60% of the AGNs. It is interesting to note that the detection rate of [O I] in the starburst galaxies is much higher than is usually observed in other samples of starburst nucleus galaxies (generally on the order of 40% or less; see Coziol et al. 1997a).

In Figure 4 we present the diagnostic diagram of the ratio [O I] 6300/Hα versus [O III] 5007/Hβ. The vertical line is the [O I] strength limit, as proposed by Baldwin et al. (1981) to separate the starburst galaxies from the AGNs. This diagram confirms the nature of the LLAGNs as determined using the previous diagnostic diagram. Only one candidate (otherwise a Seyfert galaxy) has an [O I] line of a strength comparable to starburst galaxies. Three other galaxies have values with error bars that cross the boundary between the two activity classes. The fact that many starburst galaxies in our sample have an unusually strong [O I] line is consistent with previous observations suggesting that a small fraction of these galaxies show the simultaneous characteristics of an AGN and an H II region (Véron, Gonçalves, & Véron-Cetty 1996). Our result suggests that very few AGNs present the same ambiguity.

In Table 2 we list the results of our classification. The name of the objects are the same as in Table 1. Columns (2), (3), and (4) give the ratios [O III] 5007/Hβ, [N II] 6584/Hα, and [O I] 6300/Hβ, respectively. The uncertainties in these ratios were determined using Poisson statistics. In column (5) the different types of activity are described as follows: starburst galaxies (SBNGs or H II), AGNs (Seyfert 2 [Sy2] or LINER [LNR]), and LLAGNs (dSy2 or dLNR). Column (7) gives the FWHM of the Hα line. It may be interesting to note that no Seyfert type 1 galaxies were found in the groups.

2.1. The Low-Luminosity Nature of the Hidden AGNs
Rubin et al. (1991) already noted that all the elliptical and S0 galaxies in the HCGs have ionized gas. They also remarked that this phenomenon is commonly observed in samples of early-type galaxies (PJDSB). But because the emission is hidden in the strong stellar continuum, the nature of the activity in these galaxies was not clearly established. The subtraction of a template galaxy allow us to construct two different diagnostic diagrams that confirm the AGN nature of these objects. We will now verify that the AGNs in these galaxies also have a low luminosity. This will be done by comparing our candidates with the low-luminosity AGNs discovered by PJDSB.
Because we do not have the calibrated spectra of our candidates, we cannot compare their fluxes directly to those of luminous AGNs. To test our assumption, we use instead the EW of the [N II] $\lambda 6584$ line, which, by definition, is proportional to the ratio of the flux in the line divided by the stellar continuum near the line. In Figure 5 we compare the EW of the [N II] $\lambda 6584$ line as a function of the ratio [N II] $\lambda 6584$/Hz for all the galaxies in our sample with those of the low-luminosity AGNs observed by PJDSB. A very clear pattern is seen: the LLAGNs have higher [N II] $\lambda 6584$/Hz ratios and lower EW([N II] $\lambda 6584$) than the luminous AGNs and the starburst galaxies. Most importantly, the values observed for the LLAGNs are identical to those of the low-luminosity AGNs, as studied by PJDSB. It is important to realize that in this diagram there is only one way to obtain the lowest EW value possible: the flux in the line must be low, and the stellar continuum must be high. In early-type galaxies, as in the galaxies of the sample of PJDSB and in our candidates (see Fig. 7), the stellar continuum is already near maximum, which means therefore that the line flux in the galaxies of these two samples must be similar. PJDSB determined that the characteristic Hz lumi-
ness of the low-luminosity AGNs in their sample is of the order of $10^{39}$ erg s$^{-1}$ or lower. Then, by comparison, the luminosity of the AGNs in our candidates must be of the same order, which therefore confirms the low-luminosity nature of the AGNs among our objects.

3. DISCUSSION

In Table 3 we present the fraction of each type of activity observed in our sample of 82 galaxies. The LLAGNs form more than 50% of the total AGN population found in the whole sample. From the 82 galaxies studied here, only 67 galaxies are real group members (de Carvalho et al. 1997). In Table 3 it can be seen that when only group members are considered, the fraction of starburst galaxies drops, and the fraction for the other types slightly increases.

Going one step further, we can distinguish between the galaxies that reside in the “core” and those in the “halo” of the groups. As discussed by Ribeiro et al. (1997), most HCG galaxies are embedded in larger structures forming extended halos around more dense and dynamically distinct cores. As shown by Ribeiro et al., these cores may be usefully defined as the circular region around the group barycenter having mean surface brightness $\mu_B = 27$ mag arcsec$^{-2}$, which is almost the same limit used by Hickson (1982) as part of his criteria for constructing his catalog of compact groups. Table 4 shows how the 67 galaxies in the groups are distribute between core (53 galaxies) and halo (14 galaxies). It is important to note that nearly all the AGNs, that is, the LLAGNs as well as the luminous AGNs, reside in the core of the groups.

The fraction of each activity type encountered in the core regions is reported in Table 3. It can be seen that the frac-

---

**TABLE 3**

| Type           | All ($N = 82$) | Group ($N = 67$) | Core ($N = 53$) |
|----------------|---------------|-----------------|----------------|
| No Emission    | 34%           | 37.3%           | 37.8%          |
| LLAGNs         | 20%           | 20.9%           | 24.5%          |
| AGNs           | 18%           | 19.5%           | 22.6%          |
| Starbursts     | 28%           | 22.3%           | 15.1%          |
tion of starburst galaxies decreases significantly in the core of the groups, where AGNs (47.2%) and non–emission-line galaxies (37.7%) dominate. Because the star formation rate in all of these galaxies is relatively low, we further conclude that the star formation rate in the groups is generally at a lower level.

Our sample is obviously biased toward galaxies that have high S/N ratios, therefore favoring the most luminous galaxies in the groups. To verify how this bias affects our conclusions about the spatial segregation of the different activity types in the groups, we compare, in Figure 6, the absolute magnitude of all the galaxies in our sample. Here we can see that the luminosity distributions for the LLAGNs and the luminous AGNs are clearly biased toward higher values. However, Figure 6 also shows that both the non–emission-line galaxies and the starburst galaxies show a comparable distribution of luminosities. Since these two types of galaxies have different spatial locations in the groups, we may conclude that the segregation of activity types in the groups is not the result of a luminosity bias, but corresponds to a real physical effect. The fact that AGNs reside in the most luminous galaxies of the groups is consistent with studies of AGNs in the field that show that the probability of finding an AGN increases with the luminosity of the galaxy, and that low-luminosity AGNs are very common in early-type galaxies.

In Figure 7 we present the distribution of morphological types of all the galaxies in our sample. The LLAGNs reside either in elliptical or early–type spirals, whereas the luminous AGNs seem to reside mostly in early–type spirals. Figure 7 also shows that all the nonemission galaxies are early-type galaxies (E, So, or Sa). Consequently, the LLAGNs represent 36% (41% in the core) of the early–type population in the groups. This result is consistent with the fraction of LLAGNs discovered by PJDSB in their sample of luminous E and So galaxies.

4. CONCLUSION

We have shown that a significant fraction of the brightest galaxies of compact groups display some sort of activity, either starburst or AGN. Moreover, we find that about one-half of the AGN population is made up of LLAGNs, implying that AGNs are the most frequent activity types encountered in the groups.

We have further found that the AGNs—both low-luminosity and normal—reside in the most luminous and the most early-type galaxies of the groups. These two characteristics are not unique to compact groups, but are consistent with the fact that the probability of finding an AGN increases with the luminosity of the galaxy, and that low-luminosity AGNs are very common in early-type galaxies. However, we have also found that the AGNs tend to concentrate in the cores of the groups. This may be viewed as a consequence of the luminosity and/or a morphological segregation already found in the groups (Ribeiro et al. 1997). In other words, we have discovered a high fraction of AGNs in the cores of the groups, because the most luminous and early-type galaxies are more concentrated in the groups, and because the probability of finding an AGN is higher in luminous and early-type galaxies.

That the group produces some physical effects is even more obvious when we consider the starburst galaxies: the fraction of starburst galaxies drops drastically when we go from the halo to the core of the groups. It would be interesting to see if this behavior for the starburst galaxies results from a morphological bias. In Figure 7 we can see that the starburst galaxies of our sample prefer late-type spirals. Although suggestive, this result should be viewed with caution, given the scarcity of the data for these galaxies (less than 20% of the morphologies determined in our sample).

As it is, our discovery suggests that we do have, at least for the core, a sort of density-morphology-activity relation. This relation may be reminiscent of the density-morphology relation observed in denser agglomerations of galaxies. For the HCGs, this relation would suggest that the galaxies in the groups have a common history, and that their evolution was influenced by their environment.

As a working hypothesis we propose the following scenario for galaxy evolution in the HCGs. Massive galaxies

| HCG | AGN | LLAGN | H II or SBNG | No Emission | AGN | H II or SBNG or SBNG | No Emission |
|-----|-----|-------|-------------|-------------|-----|------------------|-------------|
| 04  |     |       | 1a          |             |     |                  |             |
| 16  | 1a, 2b, 5d | 3, 4c |             |             |     |                  |             |
| 19  |     |       | 1a          |             |     |                  |             |
| 22  |     | 1a     | 3, 4b       |             |     |                  |             |
| 23  |     | 3a, 5c | 4d          |             |     |                  |             |
| 40  | 4d, 5c | 1a     | 2b          |             |     |                  |             |
| 42  | 1a | 2b, 4c |             |             |     |                  |             |
| 48  |     |       | 1a          |             |     |                  | 25          |
| 62  | 1a | 2b, 3c, 4 |             |             |     |                  |             |
| 63  | 4a |       |             |             |     |                  |             |
| 64  |     | 1      |             |             |     |                  | 22          |
| 67  |     | 2b, 1a, 3 |             |             | 6   | 8, 9, 10          |
| 86  | 4c | 1a, 3b | 6d          | 7           |     |                  |             |
| 87  | 4c | 1a, 3b | 2, 5        |             |     |                  |             |
| 88  |     | 1a, 2b | 7           |             |     |                  |             |
| 90  | 1a, 4d | 9      | 2b, 3c, 6   |             |     |                  |             |
| 97  | 5, 6b | 2, 4c, 3d |             |             |     |                  | 10, 11      |
form by subsequent mergers of smaller mass systems made of gas and stars. Obviously, denser environments will accelerate this process, and the more massive galaxies will form first in the richest regions. The frequency and intensity of mergers determine the morphologies, the most massive galaxies evolving toward the most early-type morphologies. This would explain why in HCGs the most luminous galaxies are also the most concentrated and most early-type galaxies.

This formation scenario can incorporate a sequence in which the activity level changes with time. The first phase is characterized by a starburst and a Seyfert. Each merger triggers a starburst. When the mass of the galaxy is sufficiently high, or when a large amount of gas is available, the gas falls into the center of the galaxy and forms or nourishes an AGN. As the starburst fades, depending on the reservoir of gas available and on the rate of accretion, it remains either a Seyfert or a LINER. Finally, when the matter available for feeding the AGN decreases, it remains a LLAGN or a normal galaxy. This scenario would explain, for instance, the difference observed in the groups between the morphologies of the LLAGNs and the luminous AGNs. It would also explain why the cores of the groups are dominated by a high fraction of LLAGNs and nonactive early-type galaxies, since denser environments accelerate the process. The galaxies in the cores of the groups are more evolved than in the outer regions. This would explain why starburst galaxies are observed in higher number in the halo than in the core. This scenario may also explain why we do not find any Seyfert type 1 galaxies in the core, as they would be visible only at the beginning of the process.

Following this scenario, most of the activity in HCGs would have taken place sometime in the recent past, and the groups are now observed at a quiet phase of their activity.
