Multiple cardiac arrests due to Lyme carditis

ABSTRACT
The most common form of Lyme carditis (LC) are different types of conduction abnormalities, especially atrioventricular (A-V) blocks. In most cases the course of the disease is benign and when the patient is diagnosed and treated appropriately, even the most advanced forms of A-V block typically resolve within one week. Implantation of a permanent pacemaker is only exceptionally necessary. We present a case of a patient with multiple cardiac arrests due to advanced A-V block. Despite the proper diagnosis of LC and targeted antibiotic therapy, the patient was completely dependent on temporary endocavitary pacing for more than one week. Finally, implantation of a permanent pacemaker was decided, however, during the next three months, A-V conduction abnormalities gradually subsided. This made us doubt whether the decision about implantation wasn’t made prematurely. The solution came at a one-year follow-up visit when it turned out that ventricular stimulation reappeared. We believe, that if A-V conduction disturbances in the course of Lyme disease persist for more than a week despite targeted antibiotic therapy, it is most likely a sign of serious and irreversible damage to the structures of the A-V node.

Key words: permanent pacemaker, complete atrioventricular block, Lyme disease

Introduction
Lyme disease (LD) is one of the most common tick-borne diseases. Etiologic factors are species of spirochetes (Borrelia afzelii, B. garini, B. burgdorferi), which are the Gram-negative bacteria. The incubation period from infection to the onset of symptoms is usually 1–2 weeks. The first and most common presentation of the disease is erythema chronicum migrans (early localized phase, stage 1), which is seen in 70–90% of patients. It may be accompanied by unspecific symptoms of infection, such as muscle pain, fever and headache. During the next weeks occupation of different organs and systems may develop (early disseminated phase, stage 2), with most frequent affection of the skin, joints and nervous system. Chronic phase (late disseminated phase, stage 3) occurs after 2–3 years and most commonly refers to neurological and rheumatological complications [1–3]. Lyme carditis (LC) develops in less than 5% of patients infected, with a visible male predominance (3:1). The cardiovascular signs occur in early disseminated disease (stage 2), usually in the third week after infection, however, they may appear between the 7th day and the 7th month of the illness. The pathophysiology involves infiltration of bacteria and subsequent excessive immunologic response, mainly in the connective tissue of the basal part of the interventricular septum. The majority of the cases are conduction abnormalities (90%), mostly atrioventricular (A-V) blocks, however, pericarditis, myocarditis, cardiomyopathy and degenerative valvular disease have been occasionally observed [2, 4, 5]. If the infectious agent is identified and treated appropriately, even advanced forms of conduction abnormalities have a benign prognosis and disappear quickly, usually during one week [4]. Hospitalization and continuous cardiac monitoring are recommended for patients with second- or third-degree A-V block, first-degree A-V block with a PR interval >300 ms and fluctuating bundle branch blocks. The treatment of choice is intravenously administered antibiotics, preferably ceftriaxone, however, cefu-
roxime and penicillin G may be an option. Usually, two weeks of antibiotic therapy is recommended, whereas a 4-week course is recommended for chronic manifestations of Lyme disease [3, 6]. Temporary pacing may be required in unstable patients, but generally awaiting attitude is preferred. It is advisable to avoid temporary stimulation and if it is already used, it should be as short as possible [4]. Implantation of a permanent pacemaker is only exceptionally necessary [5]. Some centres use an option of applying modified transvenous temporary-permanent pacing, which is safer than temporary pacing, allows the patient to go home, and is relatively easy to remove after a few weeks. This method however it is not popular [7].

The early stage of borreliosis is evidenced by the rise in IgG titer and/or the presence of IgM [3]. There is a two-step approach in serological diagnosis, which is an initial screening test (ELISA), followed by a Western Blot carried out for reactive and equivocal ELISA samples [2, 3]. Due to delayed immune response, in the early stages of the disease serologic results may be false negative even in 50% of patients (an early diagnostic gap). Therefore negative serological tests cannot rule out the disease and in the case of clinical suspicion of LD the ELISA should be repeated, usually after 4 weeks [2]. In the late stages of Lyme disease, IgG levels are always elevated and their absence excludes the disease [2].

Diagnosis of Lyme carditis should be based primarily on the clinical presentation and an assessment of tick-exposure risk [2]. Therefore in the case of unexplained A-V conduction disturbances especially in young men, empirical antibiotic treatment is recommended [6]. The disease is then confirmed by positive Borrelia serology. There are attempts to make a general algorithm for diagnosis of LC and the Suspicious Index in Lyme Carditis score (SILC) is a novel risk score, that estimates the probability of LC in patients with A-V block [5, 8].

**Case report**

A 48-year-old man, not yet treated for any reason, was admitted to the hospital after multiple cardiac arrest episodes in the course of recurrent severe bradyarrhythmia. The patient lost consciousness and stopped breathing without any preceding symptoms. Cardiopulmonary resuscitation was undertaken by family members, then continued by an ambulance team. In ECG monitoring third-degree A-V block with escape rhythm 30/min with wide QRS complexes was found (Fig. 1A). After atropine administration, the third degree A-V block turned into a hemodynamically stable second degree A-V block and the patient regained consciousness. On the way to the hospital, however, there were many recurrent episodes of advanced A-V
While taking a detailed medical history from the patient’s wife, she could recall that he had been exposed to multiple tick bites about a month ago and 2 weeks ago she observed erythema on the skin of his thigh, the trace of which was still present at close examination. The serological diagnosis for LD was ordered. After 3 days (5th day of hospitalization) positive results were received - the level of specific IgG but not IgM was elevated. The results were confirmed in Western Blot analysis (Tab. 1). In subsequent serological tests, that were repeated after a week, IgM was again negative but increasing IgG titers were observed. Finally, LD with heart involvement was recognized so intravenous ceftriaxone therapy (2g iv once daily) was continued for 2 weeks. As blood cultures appeared to be negative, two other antibiotics were discontinued.

Despite several days of ceftriaxone therapy, the patient was completely dependent on endocavitary pacing. Finally, for suspicion of permanent damage to the conductive system and the history of multiple cardiac arrest episodes, on the 10th day of hospitalization, a decision was made to implant a permanent pacemaker (Fig. 1B). The pacing percentage in atrial and ventricular channels at discharge (14th day of hospitalization and antibiotic therapy) was 7 and 100% respectively. In pacemaker follow-up after one and three months, gradual A-V block regression and resolution of the pacemaker’s participation in A-V conduction were observed, however, in a one-year follow-up, ventricular pacing again became visible (Tab. 2). In ECG made during the follow-up visits, normal sinus rhythm with a left posterior fascicular block (LPFB) was present, it is not certain, however, whether it is a remnant of the disease or the patient had it before (Fig. 1C).
Discussion

Plenty of cases of patients with advanced A-V blocks were published, but in a few cases, the course of the disease was so dramatic as in the presented patient case [9, 10]. In the majority of cases, antibiotic therapy was the only method of treatment and there was no need for temporary pacing nor permanent pacemaker implantation. In a systematic review made by Besant G et al. high-degree A-V block resolved in 94.3% of cases, with a median time to resolution of 5 days (3–9). A permanent pacemaker was implanted in 12.5% of patients, but in half of them, A-V block resolved after a course of antibiotics, and the pacemaker was removed or no longer required [8]. In another review, permanent pacing was necessary for 4.4% of patients [9]. Therefore, because of a known good prognosis and resolution of conduction abnormalities in most cases, the decision to implant a permanent pacemaker was not easy and not obvious. The pros were: extremely severe symptoms on admission, lack of IgM (not really an early stage of the disease?) and the need for temporary pacing for 10 days despite proper treatment. The latter mentioned might indicate permanent A-V conduction damage and additionally was associated with the patient’s impaired mobility due to the risk of electrode dislocation and possible drawbacks, including infectious complications and mechanical, like perforation of the myocardium. As on discharge (14th day of antibiotic therapy), the patient was still pacemaker dependent, the decision seemed right at first, however, during the next three months A-V conduction disturbances gradually resolved. As there are no general guidelines concerning this topic, a question came up, whether the performed management was optimal. Should the decision about pacemaker implantation be deferred? Also, another puzzling issue arose — should pacemaker removal be considered since A-V block resolved? Taking into account that the residual LPFB might be a remnant of LC — would it be fully safe to remove the pacemaker? Does LPFB increase the patient’s future risk of A-V block recurrence? No such data are available, which made the decision more difficult. The solution came with a follow-up visit a year after pacemaker implantation when it turned out that despite pacemaker settings promoting the patient’s ventricular beats (interval between an atrial paced or sensed event and the ventricular pacing pulse was about 350 ms), the ventricular pacing was again present. It was 4%, which seems a small percentage, but actually, it is enough to lead to sudden cardiac arrest.

Conclusions

The most common form of LC is A-V blocks, which usually disappear during the first few days of antibiotic therapy. In some cases, however, the A-V conduction disturbances are severe, they last longer and can be even the cause of sudden cardiac death. Persistence of A-V blocks despite antibiotic therapy for more than one week rather indicate permanent damage to the structures of the conducting system and may indicate the need for permanent pacing. As there are no guidelines concerning the timing for the pacemaker implantation, management of the most severe patients should be individual.
