Abstract. Presenilin 1 (PS1) is the causative gene for an autosomal dominant familial Alzheimer’s disease (AD) mapped to chromosome 14. Here we show that QM/J un-interacting factor (J if)-1, a negative regulator of c-Jun, is a candidate to mediate the function of PS1 in the cell. We screened for proteins that bind to PS1 from a human embryonic brain cDNA library using the two-hybrid method and isolated one clone encoding the QM/J if-1 gene. The binding of QM/J if-1 to full-length PS1 was confirmed in vitro by pull-down assay, and in vivo by immunoprecipitation assays with human samples, including AD brains. Immunoelectronmicroscopic analysis showed that QM/J if-1 and PS1 are colocalized at the endoplasmic reticulum, and the nuclear matrix in human brain neurons. Chloramphenicol acetyltransferase assays in F9 cells showed that PS1 suppresses transactivation by c-Jun/c-Jun but not by c-Jun/c-Fos heterodimers, consistent with the reported function of QM/J if-1. By monitoring fluorescent recombinant protein and by gel mobility shift assays, PS1 was shown to accelerate the translocation of QM from the cytoplasm to the nucleus and to thereby suppress the binding of c-Jun homodimer to 12-O-tetradecanoylphorbol-13-acetate (TPA)-responsive element (TRE). PS1 suppressed c-Jun-associated apoptosis by retinoic acid in F9 embryonic carcinoma cells, whereas this suppression of apoptosis is attenuated by mutation in PS1. Collectively, the novel function of PS1 via QM/J if-1 influences c-Jun-mediated transcription and apoptosis.

Key words: Alzheimer’s disease • presenilin-1 • c-Jun • cell death • Q M/J if-1

Mutations in the presenilin 1 (PS1) gene have been shown to influence the intracellular metabolism of β-amyloid (A β) and increase the ratio of A β1-42 peptides, which appears to be more fibrilligenic than A β1-40 in patient plasma as well as in brains of transgenic mice (for reviews see Hardy, 1997; Selkoe, 1997; Masters and Beyreuther, 1998). Furthermore, amyloid deposits are actually formed earlier in doubly transgenic mice coexpressing mutant PS1 and mutant amyloid precursor protein (APP) than in age-matched mice (Borchelt et al., 1997; Holcomb et al., 1997), consistent with human Alzheimer’s disease (AD) pathology.

In addition to the gained function of mutant genes, PS1 is physiologically indispensable for embryonic morphogenesis. PS1+/- mice exhibited abnormal patterning of the axial skeleton and spinal ganglia and developed cerebral cavitation (Shen et al., 1997; Wong et al., 1997). PS1 is a multipass transmembrane protein homologous to SE L-12, a Caenorhabditis elegans protein that mediates the signaling from Notch/Lin-12 family cell surface receptors (Levine and Greenwald, 1995), and has been localized to endoplasmic reticulum (Kovacs et al., 1996), Golgi apparatus (Kovacs et al., 1996), nuclear membrane (Li et al., 1997),
and plasma membrane (Dewji and Singer, 1997). PS1 is proteolytically cleaved into two fragments (Thinakaran et al., 1996), then presumably degraded by proteasome (Kim et al., 1997). During development, mutant PS1 molecules appear to function normally, because before the onset of disease, neither morphological nor functional abnormalities are observed in patients associated with the PS1 mutations.

Functional analyses of PS1 still remain controversial. PS1 was shown to participate directly in the cleavage of Aβ (Wolfe et al., 1999). Meanwhile, a number of molecules, including calneulin (Buxbaum et al., 1998), β-catenin (Zhang, Z., et al., 1998), filamin (Zhang, W., et al., 1998), and tau (Takashima et al., 1998), were reported to bind to PS1, some of which were assumed to affect cell death signaling. Furthermore, although amyloid plaque formation has been thought to be a central event in the pathogenesis of AD, it was reported that neuronal death enhanced by mutant PS1 transgene precedes extracellular amyloid deposition in aged transgenic mice (Chui et al., 1999).

Therefore, it is necessary to further characterize molecules interacting with PS1 in order to understand the mechanism underlying this complex and wide spectrum of cellular functions for the PS1 molecule. In this study, we found that QM/J un-interacting factor (Jif)-1 (Dowdy et al., 1991; Monteclaro and Vogt, 1993), a transcription factor found that QM/Jun-interacting factor (Jif)-1 (Dowdy et al., 1999). The Journal of Cell Biology, Volume 147, 1999 122

Pull Down Assay

E xpression vectors of various forms of PS1 as well as glutathione S-transferase (GST)–QM fusion proteins were constructed as follows. Full-length PS1 cDNA was amplified with primers F182 (5'-AACTCGAGTCTTATAAGTTGGTCAATGAC, nt 232–254) and R182 (5'-AAATCCCATGGGATTCCTAAGCGT, nt 1677–1660) from human hippocampal m RNA, and subcloned between XhoI and XbaI sites of pCIneo mammalian expression vector (Promega). The structure and sequence were confirmed by DNA sequencing and restriction site analyses. For vectors expressing GST fusion proteins in Escherichia coli, QM cDNA was subcloned between BamHI and EcoRI and pGEX 3X (A mersham Pharmacia Biotech) by using PCR with synthetic primers to adjust the reading frame. Fusion proteins linked to deleted QM (see Fig. 2 c) was constructed similarly by using PCR. PS1 protein was synthesized and radiolabeled with [35S]methionine (NEN) by in vitro transcription and translation with TNT T7/T3–coupled reticulocyte lysate system (Promega). Interaction between PS1 and GST–QM proteins was performed according to the reported method (Chen et al., 1997).

Immunoelectronmicroscopy

5 mm3 of tissue was obtained from the cerebral cortex of a 37-yr-old woman 24 h after her death by loss of blood, and fixed with 4% paraformaldehyde. Sections for electronmicroscopic immunocytochemistry were postfixied in 1% osmium tetroxide, stained with 2% uranyl acetate, dehydrated using graded alcohol and propylene oxide, and embedded in Eponate 12 resin. 40-μm sections were stained by rat mab against PS121–80 (Lah et al., 1997) at 1:100–500 dilution, and anti-QM polyclonal rabbit antibody (Santa Cruz Biotechnology), then detected with ECL Western blotting analysis system (Amersham Pharmacia Biotech).

Chloraphenoloc A E ty ltransferase Assay

Transfection was performed as described previously (Okamoto et al., 1990; Okazawa et al., 1991). 0.1 μg of reporter plasmid and 10–20 μg of effector plasmids were used. 10–20 μg pBluescript K S+ (Stratagene) was added to equilibrate the total amount of plasmids for transfection. Construction of effector and reporter plasmids was reported previously (Angel et al., 1987). Efficiency of transfection was verified by pC110 (A mersham Pharmacia Biotech), a eukaryotic vector containing the simian virus early promoter and E. coli–β-galactosidase (LaCZ) structural gene. Each experiment was repeated at least four times and variation of transfection efficiency was < 20%.

Enhanced Green Fluorescent Protein Fusion Protein Expression Vectors

Expression vectors of fluorescent protein-QM fusion proteins were constructed by inserting various forms of QM cDNA into pEGFPN1 (Clontech). Full-length QM cDNA was amplified by RT-PCR from human amygdala m RNA with the primers QMFi (AAAGAATTCCTCTAAATGGCACGCCGCTGGGGCCCTGTT) and QMR (AATGGATCCTGTAAGTGCAGGAGGGCCGCCCA), and subcloned between EcoRI and BamHI sites of pEGFP N1.
Ps1 suppresses c-Jun, as a Binding Protein to Ps1

Results

Identification of QM/Jif-1, a Negative Regulator of c-Jun, as a Binding Protein to PS1

We have investigated the function of PS1 by isolating the molecules that interact with PS1. We screened a human embryonic brain library using the yeast two-hybrid system. A first double screen using leucine-deficient plates and X-gal plates, we finally judged six clones showing strong interaction to be positive. In our experience with the two-hybrid system, this number of positive clones was small compared with other baits. Among them, we found a clone identical to QM/Jif-1. This molecule was isolated originally as a putative Wilms’s tumor suppressor gene (Dowdy et al., 1991), then described as a transcription factor that interacts with c-Jun and inhibits its transcriptional activation (Monteclaro and Vogt, 1993). Recently, it was shown to be identical to a ribosomal protein, L10 (Chan et al., 1996), which was therefore suggested to be a ribosomal protein possessing multiple extraribosomal functions (Wool, 1996).

This clone (PS309-4) lacked an NH2-terminal portion of 43 amino acids and encoded a variant Ser202Asn (Fig. 1 a). QM/Jif-1 does not possess a leucine zipper but might compose a C2H2-type zinc finger (Fig. 1 a). Retransformation of EGY48 yeast cells by pEGPS1 and pGSPS309-4 plasmids showed high β-galactosidase activities in independent yeast colonies (Fig. 1 b).

To determine the binding domain of PS1 molecule to QM/Jif-1, we performed deletion analysis of PS1 by two-
hybrid assay. cDNAs corresponding to various regions of the PS1 molecule were subcloned into the pEG vector and cotransfected with pJG309-4 into yeast cells. Interestingly, any partial sequence of PS1 did not bind strongly to QM/Jif-1. Instead, full-length PS1 showed a strong interaction with QM/Jif-1 (Fig. 1 c). This finding corresponds well to the results of Western blot analysis using human brains described below.

**In Vivo Interaction between QM/Jif-1 and PS1**

To verify the interaction between QM and PS1 in vivo, we performed immunoprecipitation assay with human brains, including those of familial and nonfamilial AD patients. Approximately 50 kD full-length PS1 was detected in the precipitates by αN and by αL from normal, disease control (amyotrophic lateral sclerosis), nonfamilial AD, and PS1-linked AD brains (Fig. 2 a), whereas we could not observe clear bands corresponding to the cleaved PS1 fragments. This result in human brain, together with the results from two-hybrid deletion analyses (Fig. 1 c), suggest that multiple regions in the full-length structure of PS1 are necessary for tight interaction with QM/Jif-1. This idea might have some relationship to the recent finding that NH₂- and COOH-terminal PS1 fragments reassociate and form a stable complex (Capell et al., 1998; Thinakaran et al., 1998).

Interestingly, the band was visible but very weak in lanes 6 and 7 loaded with samples from PS1-linked AD patients (Fig. 2 a). Compared with the PS1 bands in Western blot analysis using the same brain samples (Fig. 2 b), it is not due to difference of the PS1 protein amounts among brain samples. Instead, it could be due to the difference of residual neurons where QM and PS1 may interact, among samples, or due to the difference in affinity of QM to normal and mutant PS1. In the reverse immunoprecipitation assay, we detected QM in precipitates by αN as well as by αL (Fig. 2 c), reconfirming the interaction between PS1 and QM/Jif1 in vivo. We performed immunoprecipitation with nonimmune sera and with several nonspecific antisera using the same brain samples, but did not find QM or PS1 in the precipitates (data not shown).

**PS1 and QM/Jif-1 Colocalize in Cortical Neurons**

To observe the interaction between QM and PS1 in the brain morphologically, we performed immunohistochemical analyses. As QM expression has not been reported previously, we confirmed that the QM message is widely expressed in the brain by Northern blot analysis (Fig. 3). At the light microscopic level, anti-QM polyclonal antibody stained the cytoplasm of neurons in the mouse cerebral cortex (Fig. 4 a). To further characterize subcellular localization of the QM protein, we observed the mouse brain sample with electronmicroscopy and found that regions very close to tubular membrane structures, which possessed features of smooth endoplasmic reticulum, were predominantly stained (Fig. 4 b and c). This subcellular localization of QM was exactly like that of PS1 reported to date (Lah et al., 1997).

Next, we asked whether the QM and PS1 proteins are colocalized in the human brain neurons. Immunohistochemical analysis was performed with secondary antiseris conjugated to different sizes of gold particles and with the brain of a 37-yr-old woman who died due to loss of blood. We observed that the 5-nm grain of PS1 and 10-nm grain of QM were located very close to each other at the edge of smooth membrane structures in the cytoplasm of cortical neurons (Fig. 4 d). Most of those structures seemed to be smooth endoplasmic reticulum, whereas some of them possessed the features of Golgi apparatus (data not shown). Fewer grains were observed also in the nucleus (Fig. 4 e). Although the immunoreactivity was further reduced in the formaldehyde-fixed and paraffin-embedded tissues of nonfamilial or PS1-linked AD brains, we re-
peatedly found that these two grains were colocalized at membrane structure in the cytoplasm (Fig. 4, f–i).

**PSI Suppresses the Action of c-jun Homodimer**

Next, we investigated the biological significance of the interaction between QM/Jif-1 and PS1. Jif-1 was isolated as a protein binding to c-Jun from a cDNA library screened with biotinylated c-Jun (Monteclaro and Vogt, 1993). Work by Monteclaro and Vogt on the function of Jif-1 has shown that GST–QM/Jif-1 fusion proteins do not bind to 12-O-tetradecanoylphorbol-13-acetate (TPA)–responsive element (TRE) in gel mobility shift assays, but prevent the binding of a c-Jun homodimer to the TRE (Monteclaro and Vogt, 1993). Moreover, the c-Jun/c-Fos heterodimer can override this inhibition by Jif-1. Through this binding inhibition, Jif-1 inhibits gene transactivation by c-Jun.

QM/Jif-1 is extremely conserved during evolution from yeast to mammal (Farmer et al., 1994), suggesting that this factor is essential for basic cellular functions. From these observations, we supposed that expression of PS1 might affect the function of c-Jun through interaction with QM.

To test this hypothesis, we performed cotransfection chloramphenicol acetyltransferase (CAT) assays with c-jun or c-fos expression vectors as the first effector plasmid, normal or mutant PS1 expression vectors as the second effector plasmid (Fig. 5 a), and human collagenase (−517/−42) TK CAT vector containing TRE as reporter plasmid. We used F9 embryonic carcinoma cells in the assays because they possess almost no activated protein (AP)-1 activity (Angel et al., 1988), but express enough of the QM protein (data not shown). It was difficult to predict what kind of results would emerge with the addition of the PS1 expression vector, because the binding might keep QM in the endoplasmic reticulum where PS1 is most abundant (Kovacs et al., 1996), or it might assist the transport of QM to the nucleus where PS1 immunoreactivity is also detected (Li et al., 1997). It could be that cotransfection might not affect CAT activities due to a nonfunctional binding between the two molecules.

Among these possibilities, we obtained the simplest and clearest outcome. c-jun or c-jun/c-fos transactivated the CAT gene expression (Fig. 5 b) as expected. The transactivation by c-Jun homodimer was suppressed by normal PS1 as well as mutant PS1, whereas the transactivation by c-Jun/c-Fos heterodimer was not affected by adding PS1 expression vectors (Fig. 5, a and b). This suppressive effect was considered to be specific, because overexpression of a multipass transmembrane protein, glucose transporter 1 (GLUT1), which is known to move from the endoplasmic reticulum to the Golgi apparatus, did not suppress CAT activity (Fig. 5 b). The weak transactivation by c-Fos, which might have been induced with a weak endogenous c-Jun activity, was not influenced by either normal or mutant PS1. These observations corresponded very well with the interacting behavior of QM to AP-1 molecules reported previously (Monteclaro and Vogt, 1993). The suppression by mutant PS1 seemed weaker than that by normal PS1 (Fig. 5 b).

To examine whether the effect of PS1 is mediated by TRE, we changed the reporter plasmid to those that contained only TRE (Fig. 5 a). As expected, PS1 reproduced
suppression of the c-jun-mediated transactivation in collagenase 1× TRE CAT and metallothionein IIa 1× TRE CAT (Fig. 5 c). These results supported our hypothesis that PS1 affects gene regulation by c-jun through TRE. Interestingly, by using 1× TRE CAT plasmids, we observed more clearly that the suppression of c-jun-induced transactivation was weaker in mutant PS1 than in normal PS1 (Fig. 5 c).

**PS1 Represses Transactivation by junD but Not by junB**

Second, we tested whether PS1 affects transcriptional regulation by the other c-jun family members forming an AP-1 complex. Expression of junB and junD enhanced transcription from collagenase 1× TRE CAT reporter plasmid (Fig. 5 d). Transactivation by junD was clearly suppressed by expression of normal and mutant PS1, whereas transactivation by junB was not affected (Fig. 5 d). In this case, suppression of junD-mediated transactivation by normal PS1 was not remarkably different from that by mutant PS1 (Fig. 5 d), in contrast to our observations with c-jun-mediated transactivation (Fig. 5, b and c). In the CAT assays described above, we confirmed that expression of the c-jun protein was not influenced by cotransflecting PS1, and that expression of normal and mutant PS1 proteins was equivalent (Fig. 5 e). We summarized results from all the CAT assays described above with a histogram showing mean fold transactivations (Fig. 5 f).

**PS1 Promotes Translocation of QM/Jif-1 to the Nucleus**

From the data described above, we hypothesized that PS1 somehow promotes translocation of the QM protein from...
Figure 5. (a) Constructions of PS1 expression vectors and 1× TRE CAT plasmids. PS1 cDNA s were subcloned into pCl neo directed by the cytomegalovirus immediate early enhancer/promoter. For 1× TRE CAT plasmids, synthetic oligonucleotides were inserted into tkCAT. (b) CAT assay showing the effect of normal or mutant (Met146Leu) PS1 on c-jun-, c-fos-, or c-jun/c-fos-mediated transactivation. Expression of normal as well as mutant PS1 repressed transactivation of the collagenase gene enhancer/promoter by c-jun but not by c-fos or c-jun/c-fos. As control, effect of GLUT1 on c-jun–induced transactivation was examined. pBluescript KS was added to equilibrate total amounts of plasmids. (c) CAT assay using various 1× TRE CAT reporter plasmids. Cotransfection of PS1 clearly suppressed transactivation by c-jun on 1× TRE vectors. (d) CAT assay using junB and junD expression vectors. PS1 expression suppressed junD-induced transactivation but not junB-induced transactivation. (e) Protein expression of c-Jun and of normal or mutant PS1 in transfected cells used for CAT assays. Proteins were prepared from the cells used for CAT assays, separated by SDS-PAGE, and detected by anti-c-Jun antibody (αJun) or by anti-PS1-loop antibody (αPS1L). The bands corresponding to c-Jun, full-length PS1, and COOH-terminal fragment of PS1 were indicated by arrowheads. Lanes 1–4 correspond to lanes 1–4 in b. (f) Histogram showing the mean fold transactivation of multiple assays.
the cytoplasm to the nucleus, inhibits the binding of c-jun homodimer to TRE, and thereby suppresses transactivation by c-jun. We used a fluorescent protein (enhanced green fluorescent protein [EGFP]) fusion reporter plasmid to observe how intracellular transport of the QM protein is modulated by PS1, and observed that translocation of the fusion protein to the nucleus is actually accelerated by cotransfecting PS1 (Fig. 6 a). On the other hand, coexpression of mutant (Met146Leu) PS1 did not remarkably promote the nuclear translocation.

It is interesting to note that the effects of PS1 on transcription and on protein transport were remarkable although the expression level of PS1 was not as high as that of PS1 (Fig. 5 e), or as the endogenous expression level of QM/Jif-1 (data not shown). Considered with the function of PS1 assisting the nuclear transport of QM, transfected PS1 molecule might be recycled efficiently in cells, leading to the remarkable effect on c-jun function via QM protein translocated to and accumulated in the nucleus.

Next, we performed gel mobility shift assays by using nuclear extracts prepared from F9 cells expressing AP-1 transcription factors with or without PS1. We found that PS1 suppresses the binding of c-jun homodimer to TRE and very weakly suppresses that of JunD homodimer but not that of c-Jun/c-Fos heterodimer or JunB homodimer (Fig. 6 b). Furthermore, normal PS1 suppressed the binding to TRE more efficiently than mutant PS1 (Fig. 6 b). These findings are consistent with the results in CAT assay (Fig. 5, a–f) and support the idea that the nuclear translocation of QM/Jif-1 is promoted by normal PS1 thereby inhibiting the binding of c-jun homodimer, whereas mutant PS1 suppressed weakly.

We tested another possibility that PS1 inhibits JNK and thereby suppresses transactivation by c-jun (for review see Minden and Karin, 1997). T7-Tag-JNK1 expression vector was cotransfected with PS1, immunoprecipitated, and the JNK activity was tested with c-Jun produced in bacteria as a substrate. In this assay, we observed no change of JNK activity (data not shown). This finding indicates that PS1 represses the function of c-jun predominantly through the transport of QM/Jif-1, but not through c-jun phosphorylation by JNK, although further analyses are necessary to determine whether or not JNK is partially involved in the suppression by PS1.

**Mutation Attenuates Inhibition of c-jun–Mediated Apoptosis by PS1**

c-jun had been characterized as a protooncogene promoting cellular proliferation, whereas recent data indicate that c-jun is involved in some types of apoptosis. Expression of c-jun dominant negative mutants protects sympathetic neurons against cell death induced by NGF withdrawal,
and the overexpression of c-jun itself triggers apoptosis in sympathetic neurons (H am et al., 1995). Transfection of a recombinant fusion protein chimera of c-jun and hormone binding domain of estrogen receptor induces apoptosis in NIH 3T3 cells with β-estradiol added to the culture medium (Bossy-Wetzel et al., 1997). Furthermore, induction of c-fos is noted as an early event of programmed cell death (Smye ney et al., 1993), and c-fos is implicated in light-induced retinal degeneration (Hafezi et al., 1997). Interestingly, the time course of the protein expression in neuronal apoptosis induced by withdrawal of trophic factor was different. c-jun is upregulated at first and c-fos follows it; expression of junD does not change (H am et al., 1995). These findings indicated that A P-1 plays important roles in cell death, although each member of the A P-1 complex might play a different role.

Considering these previous data, we examined whether PS1 affects c-jun–mediated apoptosis. We used F9 cells for this analysis, since retinoic acid treatment induces apoptosis (A tencia et al., 1994) and upregulation of the c-jun expression (Y amaguchi-Iwai et al., 1990). Suppression of c-jun by the antisense transcript expression reduced the retinoic acid–induced apoptosis (Fig. 7 a), indicating that c-jun mediates this type of cell death. Thus, we made stable transformants expressing >10 times the amount of PS1 protein than parental F9 cells (Fig. 7 b), and observed the effect of PS1 on retinoic acid–induced apoptosis. A poptotic cells were detected by nick end labeling assay with terminal transferase (Fig. 7 c) and by trypan blue dye exclusion ass ay (Fig. 7 d) then analyzed statistically (Fig. 7 d). Normal PS1 significantly suppressed the percentage of apoptotic cells, whereas mutant PS1 suppressed it rather weakly. These results were consistently observed in the stable cell lines with high expression (n = 3). In addition, we confirmed these results by D N A fragmentation in cellular nuclei (Fig. 7 e). The weak antiapoptotic effect of mutant PS1 corresponds well to its weak suppressive effect on c-jun–induced transactivation in CAT assays (Fig. 5, b, c, and f).

The Putative Zinc Finger Domain Is Essential for Interaction with PS1

A t the end of this study, we investigated the role of the putative zinc finger domain (zif) of Q M/Jif-1 in interaction with PS1, in transcriptional regulation, and in apoptosis. First, we made various deletion constructs of Q M/Jif-1 (Fig. 8 a) and tested their binding to PS1 by pull-down assay. Normal or mutant (Met146Leu) PS1 radiolabeled with [35S]methionine by in vitro transcription/translation were interacted with GST fusion proteins of Q M in vitro and pulled down by glutathione Sepharose 4B. Full-length Q M interacted with normal PS1, whereas deletion constructs lacking zif did not bind to PS1 (Fig. 8 b), indicating that this region is essential for interaction. M utant PS1 binds to the GST-Q M fusion proteins similarly. However, the ratio between the input and the pulled-down amounts was lower in mutant PS1 (60%) than in normal PS1 (95%).

Next, we tested whether deletion of zif affects transcriptional regulation. A s Q M/Jif-1 is abundantly expressed in all the cell lines, we designed a dominant negative experiment. We selected F9PS1 cells in which transected Q M is translocated to the nucleus. Eukaryotic expression vectors containing the deletion constructs of Q M were cotransfected with c-jun, and Q M expression vectors into F9PS1 cells. Transfection of full-length Q M suppressed c-jun–induced transactivation (Fig. 8 c, lanes 2 and 3). Δ1 antagonized this suppression by Q M. The CAT activities in cotransfection of Δ1 (Fig. 8 c, lanes 4 and 5) was higher than those in c-jun–induced transactivation (Fig. 8 c, lane 2), suggesting that Δ1 antagonized endogenous Q M in addition to transected Q M. This dominant negative effect was not observed in the other constructs without zif that cannot interact with PS1 (Fig. 8 c, lanes 6–9). Therefore, Δ1 probably inhibits binding of Q M to PS1 in a competitive manner and represses the function of Q M, since Δ1 transported to the nucleus does not have a suppressive effect on c-jun. Consistently, translocation to the nucleus of the GFP fusion protein was observed in Δ1 but not in the other deletion constructs lacking zif (Fig. 8 d). Without transfecting c-jun expression vector, transactivation by Δ1 itself was not observed in F9PS1 cells, which do not express c-jun (data not shown).

Finally, we tested the role of zif in the c-jun–associated apoptosis. F9PS1 cells were transfected with the vectors expressing deleted Q M/Jif-1. Transfection of Δ1 increased the percentage of cell death induced by retinoic acid treatment, whereas the other constructs did not affect the apoptosis (Fig. 8 e). This result again showed the dominant negative effect of Δ1 on apoptosis. Collectively, it was concluded that zif is essential for the interaction of Q M with PS1 and for the effects of Q M on c-jun derived from the interaction.

Discussion

This study showed that PS1 binds to a negative cofactor of c-jun, Q M/Jif-1, and that PS1 regulates the functions of c-jun in transcription and cell death. Promotion of the nuclear translocation of Q M/Jif-1 by PS1 seems to be the underlying mechanism that connects the first and second conclusions. A specific point in our results is that Q M/Jif-1 binds to a full-length PS1. It was reported that most PS1 molecules are cleaved into two fragments which reassociate to form a heterodimer (Thinakaran et al., 1996, 1998). However, Western blot analysis in this study (Fig. 2, a and b) and in the previous reports (Lah et al., 1997) shows that full-length PS1 also exists in the brain in vivo, although the function of this form has been unclear. Our findings suggest that the full-length form also possesses a functional role related to cell viability.

So far, more than five molecules, including A PP (Waragai et al., 1997; Xia et al., 1997), calsenilin (Buxbaum et al., 1998), β-catenin (Zhang, Z., et al., 1998), filamin (Zhang, W., et al., 1998), and tau (Takashima et al., 1998), were isolated as binding proteins to PS1. The reason why many proteins bind to PS1 is not known. However, it might be explained by suggesting that PS1 functions as a kind of intracellular transporter with a relatively low specificity. The multipass transmembrane structure of PS1, especially of the full-length form, does not contradict this hypothesis, and this kind of activity was actually shown in the case of amyloid protein transport (Naruse et al., 1998). Our observation on the nuclear translocation of Q M/Jif-1 is also compatible with this idea.
Activation of c-jun, especially that mediated by JNK, has been suggested to participate in various types of cell death, including TNF- or Fas-induced apoptosis (Verheij et al., 1996). Numerous reports keep emerging on this apoptotic cascade. JNK was reported to enhance apoptosis induced by a breast cancer susceptibility gene, BRCA1, through activation of GADD45 (Harkin et al., 1999). The JNK-dependent apoptotic pathway has been implicated in the morphogenesis of Drosophila wing (A dachi-Y amada et al., 1999). Furthermore, kainic acid-induced apoptosis in the hippocampus was prevented in the mice lacking the Jnk3 gene (Y ang et al., 1997), indicating that JNK3 is essential for this type of apoptosis. The role of JNK in kainic acid-induced apoptosis was reconfirmed in the knock-in

Figure 7. (a) Retinoic acid-induced apoptosis was suppressed in stable cells expressing antisense c-jun. SDS-PAGE and Western blot analysis show that expression of the c-jun protein was induced by retinoic acid treatment in F9 cells but not in the stable cells expressing antisense c-jun. Genomic DNA analysis of these cells shows that the DNA ladder formation corresponding to apoptosis was suppressed in the antisense stable cells. Similar results were obtained in the other stable cell lines (n = 3). (b) Western blot analysis with anti-PS1 loop antibody showing PS1 protein expression level in stable cells. F9PS1, a stable cell line expressing normal PS1; F9mPS1, a stable cell line expressing mutant (Met146Leu) PS1; FL, full-length PS1; CTF, COOH-terminal fragment of PS1. (c) Nick end labeling assay showing that retinoic acid-induced apoptosis was reduced remarkably in F9PS1 but mildly in F9mPS1. Fluorescent labeling of apoptotic nuclei was performed with APO3 Detection System (Promega) according to the commercial protocol. (d) Effects of PS1 or mPS1 on retinoic acid-induced apoptosis were detected by nick end labeling assay (white bars) and by trypan blue dye exclusion analysis (shaded bars). Three independent stable cell lines were analyzed in each overexpression. Percentage of apoptosis in eight visual fields (mean ± SD) was significantly decreased (ANOVA, P < 0.01) in F9PS1 (cell lines 1-3) and F9mPS1 (cell lines 1 and 2) compared with F9. (e) Genomic DNA analysis of F9 cells and stable cells expressing normal or mutant PS1 in retinoic acid-induced apoptosis. Cells were cultured in the presence of 0.1 μM all-trans retinoic acid for 48 h. Both floating and adhering cells were collected together for DNA preparation. MM, molecular weight marker IV (Boehringer Mannheim).
mice carrying mutations at JNK-phosphorylation sites of the c-jun gene (Behrens et al., 1999). In the A D brain, the increase of c-jun immunoreactivity was observed and strongly correlated with pathological changes (Anderson et al., 1996). Mutations in PS1 might influence such cascades at the final step of c-jun and thereby affect apoptosis. Since our results showed that the inhibitory effect of mutant PS1 on c-jun-mediated apoptosis was weaker than that of normal PS1, mutation in PS1 could be a promoting factor in c-jun-mediated apoptosis.

However, there remain debates on the role of c-jun and JNK in the in vivo apoptosis. A though double gene disruption of Jnk1 and Jnk2 leads to severe dysregulation of apoptosis during development at specific regions in the brain, Jnk3 does not affect this apoptosis (Kuan et al., 1999). c-jun was reported to be dispensable in developmental cell death and axogenesis of the retina (H erzog et al., 1999). These discrepancies might suggest that the c-jun/JNK cascade plays different roles in the developmental neuronal death and in the death of the mature neuron. Therefore, our results on the cascade from PS1 to c-jun should be applied carefully to different types of cell death.

The functions of normal and mutant PS1 in cell death reported so far are still difficult to combine (for review see Barinaga, 1998). Normal PS1 had been reported to promote cell death basically via affecting the A β metabolism. Meanwhile, accumulating data from independent laboratories indicated that PS1 also modifies various cell death cascades. It suppresses apoptosis associated with p53 and p120Raf activation (Roperch et al., 1998) and promotes the antiapoptotic function of β-catenin (Zhang, Z., et al., 1998). In these cases, normal PS1 suppresses cell death, whereas mutations in PS1 abort this function.

Suppression of c-jun homodimer by PS1 might lead to a different outcome in signaling pathways other than the c-jun-mediated apoptosis examined in this study. For example, neurotrophins bind to tyrosine kinase-type membrane receptors and activate c-jun through the mitogen-activated protein (MAP) kinase pathway. Many other trophic factors, including fibroblast (FGF), epidermal (EGF), platelet-derived (PDGF), and hepatocyte growth factors (HGF), induce similar signaling cascades and promote cell survival. In such a condition where the activation of c-jun mainly contributes to survival, PS1 might promote apoptosis. Like neurotrophins which transduce survival and death signalings via the high affinity and low affinity receptors, respectively (for review see Dechant and Barde, 1997), PS1 might transduce both types of signalings via different molecules binding to PS1.

In other words, our results might have proposed another type of explanation for why PS1 induces diverse effects on the cell fate. The PS1/QM/c-jun cascade leads to the oppo-
site outcome, survival or death, depending on the final effec-
tive of c-jun, which is influenced by conditions. A cellular
though it is not yet known which factors define the attitude
of c-jun in cells, other types of signaling cascades induced by
PS1, including calcium release from endoplasmic reticu-
lum (Guo et al., 1996) and G protein signaling (for review
see Nishimoto, 1998), might cross-talk and change the
responding manner of cells to the c-jun activation.

In the AD brains, which usually degenerate for more
than several years, it is possible that both c-jun-associated
and c-jun–nonassociated neuronal deaths occur in various
situations. Although apoptosis itself is a rather rapid pro-
cess in a single neuron, it occurs in numerous neurons of
the brain at random and so the mass degeneration of the
brain proceeds gradually. Therefore, we are speculating
that c-jun–mediated apoptosis influenced by PS1 might be
an additive factor to modify neuronal fate in the AD brain,
and could function in parallel with the amyloid deposition
promoted by PS mutations as well as the pathogenic me-
chanisms mediated by other binding proteins.
