Helicobacter species have been found in human bile and biliary tract (BT) tissue and are suspected to cause BT diseases, including gallbladder and extrahepatic cancers, collectively referred to in this work as BT cancers. We conducted a literature review of the epidemiological evidence linking the presence of Helicobacter species in bile or BT biopsies to BT cancers and benign diseases. Reports showed great variability with respect to study methods. Nine studies of BT cancers were identified, all with 30 or fewer BT cancers; eight included cancer-free control subjects and used polymerase chain reaction (PCR) as a means of Helicobacter species detection. In four of these studies, Helicobacter species were detected in patients with BT cancer significantly more frequently than in controls, at least when controls without BT diseases were used. In two studies, no Helicobacter species were detected in either cases or controls. Helicobacter species were also often detected in benign BT diseases such as gallstone disease or chronic cholecystitis. As our current knowledge relies on a few small studies that showed substantial differences, larger studies and more standardised protocols for detecting DNA and antibodies against Helicobacter species are needed to investigate a potential association with BT cancer.

Keywords: Helicobacter; biliary tract neoplasms; gallbladder neoplasms; gallstones; cholecystitis

Gallbladder cancers (ICD-10 code C23) and extrahepatic biliary tract cancers (code C24, hereafter referred to collectively as biliary tract (BT) cancers) are relatively rare malignancies with wide variations in incidence rates worldwide (Figure 1). The highest BT cancer incidence rates are seen within Latin America (e.g., up to 93.3 per 100,000 for men and 25.3 per 100,000 for women in Chile), but the disease is also frequent in Northern India, Japan, Korea, and some Eastern European countries (Curado et al., 2007). Although gallbladder cancer is the most common BT cancer, its overall incidence, and its proportion of all BT cancer, varies substantially across regions and genders (e.g., 18.9% among men in Denmark and 93.6% among women in New Delhi, India, respectively) were also searched. Finally, we reviewed the reference lists of all identified relevant studies. No restrictions on date or study design were applied. After exclusion of case-series with fewer than five patients or biological specimens, we retained all relevant human studies on BT cancer and their possible or proven precursor lesions published up to January 2008.

For the sake of accuracy and comparability, only the following methods of direct Helicobacter species detection in bile, gallstones, or tissue biopsies were considered for the review: (1) amplification by polymerase chain reaction (PCR), (2) histology (histopathology, immunohistopathology), and (3) culture. For each of the studies selected in this review, the following was retrieved whenever possible:

**MATERIALS AND METHODS**

We carried out several detailed searches of the database MEDLINE through PUBMED, using the following entry terms in the first search round: ('Gallbladder Neoplasms'[Mesh] OR 'Gallbladder' [Mesh] OR 'Gallbladder Diseases'[Mesh] OR Gallbladder [Text Word]) AND ('Helicobacter'[Mesh] OR 'Helicobacter Infections'[Mesh] OR 'Helicobacter pylori'[Mesh] OR 'Helicobacter hepaticus'[Mesh]). We then repeated the search using 'Biliary tract neoplasms', 'Cholangiocarcinoma', 'Cholelithiasis', 'Cholecystitis', and 'Gallstone' as entry terms instead of 'Gallbladder neoplasms'. Other MEDLINE searches were subsequently carried out using 'Helicobacter bilis' and 'Helicobacter pullorum' as single entry terms. Regional databases for India, Southeast Asia, and Latin America (the Index Medicus for South-East Asia Region (IMSEAR), Latin American and Caribbean Centre on Health Sciences Information (LILACS) and Indian Medlars Center National Informatics Centre (INDMED) databases, respectively) were also searched. Finally, we reviewed the reference lists of all identified relevant studies. No restrictions on date or publication language were applied. After exclusion of case-series with fewer than five patients or biological specimens, we retained all relevant human studies on BT cancer and their possible or proven precursor lesions published up to January 2008.

Helicobacter pylori (H. pylori) infection is a well-established cause of stomach cancer (Amieva and El-Omar, 2008). Since the discovery of H. pylori in 1982, 30 other Helicobacter species have been isolated from the stomach, intestinal tract, and liver of mammals and birds. A few species found in human bile and BT tissue biopsies (Helicobacter bilis (H. bilis), Helicobacter pullorum (H. pullorum), Helicobacter hepaticus (H. hepaticus), and H. pylori) have been suspected to cause BT diseases. We aimed to review current information on Helicobacter species in BT cancer and benign BT diseases in humans and to help delineate future research needs on the topic.

available: location and year of data collection, histological diagnosis, age and gender of BT cancer cases, type of biological specimen, method of *Helicobacter* species detection, type of *Helicobacter* species identified, and selection criteria of control subjects, if present.

**RESULTS**

*Helicobacter* species and BT cancers

Nine studies (Table 1) that investigated the presence of *Helicobacter* species in the bile or BT tissue biopsies of patients with BT cancers were identified (Roe et al, 1999; Fukuda et al, 2002; Matsukura et al, 2002; Bulajic et al, 2002a; Fallone et al, 2003; Murata et al, 2004; Pradhan and Dali, 2004; Kobayashi et al, 2005; Bohr et al, 2007). Eight studies used PCR as one of the means of *Helicobacter* species detection. The PCR primers varied across studies, but most used genus-specific primers (such as C97-C98) as a first-line test before undertaking PCR assays that targeted different *Helicobacter* species.

Variability among PCR study findings was substantial (between 0 and 82.8% of specimens tested positive for *Helicobacter* species) even when analysis was restricted to the same type of biological specimen ( bile or tissue biopsies). Using species-specific primers, *H. bilis* was found in 35 out of 67 specimens (52.2%) from four different studies, whereas *H. hepaticus* was searched for in two studies, but only found in 4 out of 19 specimens (21.1%) in one study.

Two studies used histopathology staining to search for *Helicobacter* species in BT tissue biopsies. Although *Helicobacter*-like bacteria were detected in six out of seven BT cancers from a study in Nepal, no infections were detected in a German series of 20 BT cancers, using three different methods of staining and histoimmunochemistry. The German study also reported negative findings according to several PCR amplification methods, as well as culture, of fresh gallbladder tissue biopsies. Only one other study reported an attempt to cultivate these bacteria, but although tissue biopsies yielded positive PCR results, culture in microaerobic conditions was unsuccessful (Table 1).

Eight studies had one or more control groups allowing some comparison with cancer cases (Table 2). Controls were subjects who underwent the same procedure as cases, and were diagnosed with benign BT diseases. In three studies, a group of controls without BT diseases was also included. The presence of *Helicobacter* species in bile or BT tissue biopsies was detected significantly more often in cases than in controls in four studies, at least when controls without BT diseases were used, but none were detected in cases in two other studies (Table 2).

*Helicobacter* species and benign BT diseases

Our literature search identified 20 studies investigating the presence of *Helicobacter* species in the bile, gallstones, or BT tissue biopsies of patients with benign BT diseases (Arnaout et al, 1990; Figura et al, 1998; Fox et al, 1998; Monti et al, 1999; Rudi et al, 1999; Myung et al, 2000; Harada et al, 2001; Mendez-Sanchez et al, 2001; Monstein et al, 2002; Roosendaal et al, 2002; Bulajic et al, 2002b; Chen et al, 2003, 2007; Silva et al, 2003; Farshad et al, 2004; Abayli et al, 2005; Apostolov et al, 2005; Neri et al, 2005; Tiwari et al, 2006; Misra et al, 2007). Of these, 19 used PCR amplification methods (Table 3). The choice of primers varied across studies; some primers were based on genes coding for the 26kDa *H. pylori* protein, *UreA* or *UreB* enzymes, whereas others targeted 16S ribosomal RNA fragments, either common to all organisms of the *Helicobacter* genus, or specific to a particular species. Only in two studies, from Chile and Brazil, did the authors undertake sequencing to identify the detected species.

*Helicobacter* species were assessed by PCR in gallstones in five studies. The frequency of detection varied from 0 to 72%, and the species identified was believed to be *H. pylori* in all cases. In one study from Sweden, *H. pylori* was searched for and detected in the nucleus rather than in the envelope of the stones, suggesting an early presence of the bacteria in the process of gallstone formation (Monstein et al, 2002). Of 16 PCR studies on *Helicobacter* species in bile or BT tissue biopsies in benign BT diseases, the percentage of positive specimens varied from near 0% in five studies to close to 50% in six others, with three studies showing intermediate percentages. Two other studies reported a high prevalence: 29 out of 30 bile specimens of patients with hepatobiliary diseases were *Helicobacter* genus-positive in one study, as were 16 out of 22 gallbladder tissue biopsies of chronic cholecystitis patients in another.

Histological and/or immunohistological examination of tissue biopsies was undertaken in seven studies (including two histological series of metaplastic gallbladder sections) using various staining methods and antibodies. Helicobacter-like bacteria were seen in all but one study, and the percentage of positive specimens varied from 1 to 45%. In three studies, immunohistological staining using anti-H. pylori antibodies confirmed the histological findings. Attempts to culture the bacteria were reported in four studies, with three failing to grow any Helicobacter species from frozen specimens, despite some success with PCR or histology. In another study, however, 6 out of 77 (8%) fresh gallbladder tissue biopsies from patients with gallstones grew Helicobacter-like bacteria (Table 3).

*Fisher’s exact test, P < 0.05. *Bulajic et al (2002a) also reported age- and sex-adjusted odds ratio (9.9; 95% confidence interval: 1.4–70.5). *Five of the cases in this study were intrahepatic bile duct cancers. *In the only positive control specimen, the organism was identified as Helicobacter ganmani.
DISCUSSION

We aimed to evaluate available evidence linking Helicobacter infection with BT cancer. It became clear that our current knowledge relies mainly on a few small studies that show substantial differences in methods and results. In four studies, mainly from Japan, the detection of Helicobacter species was significantly more frequent in bile or BT tissue biopsies of cancer patients compared with controls, at least when controls without BT diseases were used. Using species-specific primers, the Helicobacter species most

*H* species identified in this study as *H* rappini was later reclassified as belonging to the *H* bilis species (Hanninen et al, 2005). Only specimens with gastric metaplasia were investigated. Only specimens *H* genus-positive by PCR were investigated. Only specimens *H* genus-positive by histology were investigated.
consistently searched for and identified from bile or BT tissue biopsies of cancer patients was \textit{H. bilis}. In two studies from Canada and Germany, however, no \textit{Helicobacter} species were detected in BT cancers, despite the use in the German study of numerous detection techniques.

The presence of \textit{Helicobacter} species, including \textit{H. pylori}, was also often detected in benign BT diseases such as gallstone disease or chronic cholecystitis, which are recognised risk factors for the development of BT cancer. However, as with BT cancer, studies of benign BT diseases showed extreme variability in methods and findings.

Lower \textit{Helicobacter} species prevalence was typically observed in western countries with low BT cancer incidence, and higher prevalence in countries with high BT cancer incidence, the best example being Japan. Whether regional variations in the prevalence of \textit{Helicobacter} species in BT cancers are real or are a result of differences in the type and quality of detection methods used is unknown.

Most findings presented here derive from PCR-based studies, the comparability of which depends on the quality of the biological specimens (bile, stone, or tissue biopsies; fresh, fixed, or frozen), the strategy chosen for \textit{Helicobacter} detection, and potential problems such as contamination and the presence of Taq polymerase inhibitors. The sensitivity and specificity of PCR are also directly dependent on the choice of primers. In early studies, primers targeting the genes encoding the 26kDa protein or the \textit{UreB} proteins were often used. Although authors believed that \textit{H. pylori} was identified, these findings may also be consistent with other \textit{Helicobacter} species. For example, it has been shown that a gene coding for the 26kDa protein is present in at least eight other \textit{Helicobacter} species (including \textit{H. bilis} and \textit{H. pullorum}) with high similarity to the gene in \textit{H. pylori} (Lundstrom et al., 2001). Similarly, urease structural genes from \textit{H. hepaticus} are highly homologous to \textit{UreA} and \textit{UreB} from \textit{H. pylori} (Shen et al., 1998). Even PCR based on the conserved 165 rRNA genes may yield different results depending on the set of primers used (Moyaert et al., 2008).

It should be noted that the available sequence information from non-\textit{H. pylori} species is still limited. Moreover, for \textit{H. pylori}, it has been shown that the intraspecies sequence variability is substantial, which may hamper uniform detection by a single set of PCR primers (Kraft et al., 2006). Therefore, it is difficult to determine whether PCR primers can distinguish \textit{Helicobacter} species, especially in patients from different geographic regions. The sensitivity of PCR is also inversely proportional to the length of the amplicon. This is particularly important in clinical materials with a high risk of DNA damage, such as formalin-fixed, paraffin-embedded tissue biopsies.

Taken together, for reliable \textit{Helicobacter} species detection and distinction, it would be advisable, although seldom done so far, to use multiple PCR primer sets at somewhat reduced annealing temperatures to permit amplification of imperfectly matching sequences. Ultimately, amplicons obtained by such PCR should be sequenced to confirm the true identity of the \textit{Helicobacter} species.

Means of detection other than PCR also have substantial drawbacks. \textit{Helicobacter} species culture has been unsuccessful in the majority of studies of BT cancer or benign BT diseases. The use of frozen specimens, which are notoriously difficult to culture, may explain some of the negative findings (Solnick and Schauer, 2001). Histology has been considered the gold standard for the detection of \textit{H. pylori} in the stomach for many years; however, few studies have assessed histological changes associated with \textit{Helicobacter} infection in the gallbladder or BT tissue. In two studies from India and China, colonisation by \textit{Helicobacter} was shown in the gallbladder epithelium, especially in the areas of gastric metaplasia (Chen et al., 2007; Misra et al., 2007), but it is not known whether this was merely a consequence of tissue damage. Serological studies have not been reviewed here, but cross-reactivity between the immune response to antigens from \textit{H. pylori} and \textit{H. bilis} has been reported (Ananieva et al., 2002; Pisani et al., 2008). Furthermore, it has been shown that the prevalence of serological and histological markers of \textit{H. pylori} decreases in gastric cancer (Camorlinga-Ponce et al., 2008) and it is not known whether the same happens in BT cancer.

An implication of \textit{Helicobacter} infection in BT cancer pathogenesis is nevertheless plausible. \textit{Helicobacter} species that can survive in, or colonise, the bile ducts may induce the formation of gallstones both directly, through the urease activity of some of the species, or indirectly through a T-cell-dependent immune response (Belzer et al., 2006; Maurer et al., 2007). The colonisation of the mucosa by bacteria may also aggravate the chronic inflammatory state already caused by gallstones (Wistuba and Gazdar, 2004; Jergens et al., 2007). In animal studies, the sequence of events going from chronic inflammation to cancer has been directly linked to some \textit{Helicobacter} species. For instance, \textit{H. hepaticus} can cause chronic active infection of bile canaliculi that progresses to liver carcinoma in A/JCr laboratory strains of mice (Ward et al., 1994). Similarly, colon cancer in SMAD-3-deficient mice is enhanced by dual infection with \textit{H. hepaticus} and \textit{H. bilis} (Maggio-Price et al., 2006).

In conclusion, further development of PCR testing protocols is required, as well as a better characterisation of antigens suitable for histoimmunochemistry. As the BT is only accessible through invasive procedure or surgery, the choice of controls who can provide adequate specimens for case–control studies is limited. Larger epidemiological studies will only be possible by developing serological methods validated against direct detection of \textit{Helicobacter} species in the gallbladder.

ACKNOWLEDGEMENTS

We thank T. Perdrix-Thoma for editorial assistance and S. Grant for help with literature searches.

Conflict of interest

The authors declared no conflict of interest.

In conclusion, the authors of the present study have reported an association between Helicobacter pylori infection and gallstone disease. The study highlights the role of H. pylori in the etiology of gallbladder disease, particularly in patients with chronic active hepatitis. Their findings have implications for the development of future diagnostic and therapeutic strategies for this common and often debilitating condition. Further research is needed to better understand the underlying mechanisms and to explore potential strategies for prevention and treatment.
