Supporting Information

ABSTRACT: ABC triblock copolymers with a poly(ethylene glycol) (PEG) midblock have attractive properties for biomedical applications because of PEG’s favorable properties regarding biocompatibility and hydrophilicity. However, easy strategies to synthesize polymers containing a PEG midblock are limited. In this study, the successful synthesis of a heterofunctional PEG macroinitiator containing both an azoinitiator and an atom transfer radical polymerization (ATRP) initiator is demonstrated. This novel PEG macroinitiator allows the development of elegant synthesis routes for PEG midblock-containing ABC copolymers that do not require protection of initiating sites or polymer end-group postmodification. Polymers with outer blocks composed of different monomers were synthesized to illustrate the versatility of this macroinitiator. N-Isopropylacrylamide (NIPAM) was included to obtain thermosensitive polymers, 2-(dimethylamino)ethyl methacrylate (DMAEMA) provided pH-sensitive properties, and 2-hydroxyethyl acrylate (HEA) functioned as a noncharged hydrophilic block that also allows for postmodifications reactions. This synthesis approach can further contribute to the design of high-precision polymers with tailorble block compositions and polymer topologies, which is highly attractive for applications in nanotechnology.

1. INTRODUCTION

Emerging technologies in the nanotechnology field have led to the development of novel polymeric materials with sophisticated properties and smart performances. In particular, block copolymers with well-defined architectures play a central role in polymer science. Control over chemical structures, compositions, and molecular characteristics of block copolymers give rise to innovative self-assembling materials. A rich variety of ordered nano- and macrostructures can be formed when two or more polymeric chains, having different physical properties, are covalently linked to each other. The synthesis of copolymers of the diblock AB type has been extensively reported in the literature. Depending on the copolymer’s composition, different ordered structures can be obtained, including lamellae, cylinders, spheres, and gyroids. The shape and size of the achieved supramolecular structure can be varied by tuning the properties of the blocks, such as hydrophobicity, presence of charged groups, or block length. In addition, the environment of the polymer, such as solvent, pH value, or temperature, can influence the self-assembly behavior of these materials.

Besides the diblock AB type materials, multiblock copolymers including ABC triblock copolymers have attracted much attention because of their unique structure with multiple different homopolymer blocks. The addition of another block leads to a much richer variety of phases, and the resulting materials have the potential to generate a wide range of multiphase structures on a mesoscopic length scale. Consequently, numerous materials for applications ranging from the development of novel surfactants, dispersants, coatings, and adhesives to materials for microelectronics and biomaterials, such as membranes and drug delivery systems, became available.

Poly(ethylene glycol) (PEG) is a neutral and hydrophilic polymer and an important component for various biomedical
hydrophilic PEG midblock, which can be of particular interest for the design of materials for biomedical applications, and outer blocks having different properties. In addition, no protection of the initiating sites during or polymer end-group modifications after the polymerization process is required.

2. MATERIALS AND METHODS

2.1. Materials. All materials were obtained from Sigma-Aldrich (Zwijndrecht, The Netherlands) and used as received unless otherwise noted. α,ω-Butyloloxycarbonylamino-ω-hydroxypoly(ethylene glycol) with PEG molecular weight of 5000 Da (Boc-NH-PEG5000-OH) was obtained from Iris Biotech GmbH (Marktredwitz, Germany) and dried overnight in a vacuum oven at room temperature (RT) before use. 4-(Dimethylamino)pyridinium-4-toluenesulfonate (DPTS) was prepared according to a literature procedure. Triethylamine (TEA) and 2,4,6-trinitrobenzenesulfonic acid (TNBSA) solution in methanol (5% w/v) were obtained from Thermo Fisher Scientific (Bleiswijk, The Netherlands). Peptide grade dichloromethane (DCM), N,N-dimethylformamide (DMF), tetrahydrofuran (THF), and diethyl ether were purchased from Biosolve (Valkenswaard, The Netherlands). All solvents were dried by molecular sieves for 24 h before use. Prior to use, 2-(dimethylamino)ethanol methacrylate (DMAEMA) was passed through a column of alumina to remove the inhibitor. Slide-A-lizer dialysis cassettes (M₉cutoff: 3.5 and 10 kDa) were obtained from Thermo Fisher Scientific (Bleiswijk, The Netherlands).

2.2. Synthesis of Heterofunctional PEG Macroinitiator. The synthesis of (Br-NH-PEG5000)-2-ABCPA was performed according to a three-step synthesis route as described in detail below.

2.2.1. Characterization of Starting Compound Boc-NH-PEG5000-OH. Prior to the synthesis, the commercially obtained Boc-protected PEG was characterized by 1H NMR by the addition of trichloroacetyl isocyanate (TAIC) to determine the M₉ of the polymer. To this end, around 5 mg of the compound was dissolved in 1 mL of deuterated chloroform, and a few drops of TAIC were added. After 15 min incubation at RT, an 1H NMR spectrum was recorded. TAIC reacts with the free hydroxyl group of the Boc-NH-PEG5000-OH thereby causing a downfield shift to δ = 4.4 ppm of the peak of the methylene group adjacent to the hydroxyl group. By comparing the integrals of the peaks at δ = 4.4 ppm and δ = 3.8–3.5 ppm (PEG), the M₉ of the polymer was calculated, and this value was used for further calculations in the synthesis steps. Furthermore, the degree of bocylation was determined by comparing the integrals of the peaks at δ = 1.4 ppm (Boc group) and δ = 3.8–3.5 ppm (PEG).

2.2.2. Synthesis of (Boc-NH-PEG5000)-2-ABCPA. Boc-NH-PEG5000-OH (1.0 g, 0.20 mmol) was dissolved in 5.0 mL of dry DCM together with 280 mg (0.10 mmol) of 4,4’-azobis(4-cyanopentanoic acid) (ABCPA) and 8.8 mg (0.03 mmol) of DPTS. The mixture was cooled on ice, and 5.0 mL of 60 mM (0.3 mmol) of N,N-dicyclohexyl-carbodiimide (DCC) in DCM was added dropwise. The reaction mixture was allowed to react for 24 h at RT under a N₂ atmosphere. Afterward, the mixture was filtered through a 0.2 μm nylon filter to remove the formed dicyclohexylurea (DCU), and the product was further purified by precipitation in cold diethyl ether (three times). 1H NMR (CDCl₃): δ (ppm) 4.25 (4H, PEG methylene next to ABCPA), 3.8–3.5 (10H, PEG, Boc), 2.2–1.6 (8H, ABCPA methylene), 1.71 + 1.64 (6H, ABCPA methyl), 1.4 (18H, Boc).

The amount of unreacted PEG was determined by 1H NMR by the addition of TAIC to the sample as described in section 2.2.1. The amount of monosubstituted Boc-NH-PEG-ABCPA present in the final product was calculated by taking the relative peak area (%) of the GPC peak at 15 min (corresponding to the 5 kDa PEG product) minus the percentage unreacted PEG as determined by 1H NMR spectroscopy.

2.2.3. Deprotection of (Boc-NH-PEG5000)-2-ABCPA. The amine groups of the macroinitiator were deprotected with an excess of trifluoroacetic acid (TFA). Therefore, 950 mg (0.19 mmol) of (Boc-NH-PEG5000)-2-ABCPA was dissolved in 10 mL of DCM/TFA (1/1, v/v) and stirred overnight at RT. Afterward, the solution was partially evaporated under reduced pressure, and the product was precipitated in cold diethyl ether (three times). 1H NMR (CDCl₃): δ (ppm) 4.25
(4H, PEG methylene next to ABCPA), 3.8–3.5 (910H, PEG), 2.2–2.6 (8H, ABCPA methylene), 1.71 + 1.64 (6H, ABCPA methyl) 1.94 (12H, methyl bromoisobutyryl).

2.3. Synthesis of ABC Triblock Polymers. The synthesis of ABC triblock polymers followed a two-step procedure, in which the first step involved atom transfer radical polymerization (ATRP) followed by free radical polymerization (FRP).

2.3.1. Synthesis of ABBA Polymers by Atom Transfer Radical Polymerization (ATRP). In a typical procedure, 1 equiv of the PEG macroinitiator, 290 equiv of N-isopropylacrylamide (NIPAM) or 278 equiv of 2-hydroxyethyl acrylate (HEA), and 8.2 equiv of CuBr were dissolved in a solvent mixture of dry DMF in an airtight Schlenk tube. TEA was added to the solution. Afterward, 89 μL of α-bromoisobutyryl bromide was added, and the mixture was allowed to react overnight at RT under N₂ atmosphere. The reaction mixture was recovered by freeze-drying with a typical yield of 80–90%.

2.3.2. Synthesis of AB Polymers by Free Radical Polymerization (FRP). In the next step, the ABBA polymer and a deprotected triblock polymer were dissolved in dry DMF in an airtight Schlenk flask. The concentration of the monomer was adjusted to 300 mg/mL. At 30 °C, the polymer solution was transferred to a dialysis cassette and dialyzed against water for 48 h at 4 °C (Mₙ cutoff: 3500 Da) and subsequently freeze-dried.

2.3.3. Synthesis of ABC Triblock Polymers. The synthesis of ABC triblock polymers followed a two-step procedure, in which the first step involved atom transfer radical polymerization (ATRP) followed by free radical polymerization (FRP).

2.4. 1H NMR Spectroscopy. The macroinitiator and polymers were characterized with 1H NMR spectroscopy on an Agilent 400 MR-Spectrometer (Agilent Technologies, Santa Clara, CA). Chemical shifts were referred to the residual solvent peak (δ = 7.26 ppm for CDCl₃, and δ = 4.80 ppm for D₂O). All data analysis was performed using MestReNova Software version 10.0.1–14719.

2.5. Gel Permeation Chromatography (GPC). The obtained products were further characterized by GPC using a Waters Alliance System (Waters Corporation, Milford, MA) equipped with a refractive index (RI) detector and a PLgel 5 μM MIXED-D column (Polymer Laboratories) using DMF containing 10 mM LiCl as eluent. The column temperature was set to 65 °C and the flow rate to 1.0 mL/min. Calibration was performed using poly(ethylene glycol) standards of narrow and defined molecular weights. All data analysis was performed using Empower 3 Software 2010.

2.6. Quantification of Primary Amines (TNBSA Assay). Free primary amine groups of the synthesized products of the PEG macroinitiator were quantified by a TNBSA assay. Samples were dissolved in sodium bicarbonate buffer (0.1 M, pH 8.5) with a concentration of 1–4 mg/mL. Glycine standards were prepared for calibration at concentrations ranging from 0 to 0.15 mM in the same buffer. Next, 250 μL of a freshly prepared 0.01% TNBSA solution in buffer was added to 500 μL of a sample or standard solution, and the solutions were incubated at 37 °C for 2 h. Afterward, 250 μL of 10% SDS and 125 μL of 1 M HCl were added to each solution, and the absorbance at 335 nm was measured in triplicate using a BMG Spectrostar nano wellplate reader. Data analysis was performed using MARS Data analysis software version 2.22 (BMG Labtech, Ortenberg, Germany).

2.7. Determination of Cloud Point (CP) of Thermosensitive Polymers. The CP of thermosensitive polymers was determined by light scattering using a Jasco FP-8300 spectrophotometer (Jasco Benelux BV., De Meern, The Netherlands). The polymers were dissolved overnight at a concentration of 2 mg/mL in 20 mM N(2-hydroxyethyl)piperazine-N’-(2-ethanesulfonic acid) (HEPES) buffer, pH 7.4. Next, 1 mL of the polymer solution was transferred to a clean glass cuvette, and the scattering intensity was measured at 550 nm while increasing the temperature from 10 to 60 °C with a heating rate of 1 °C/min. The cloud point was taken as the onset point of increasing scattering intensity.

2.8. Micelle Formation and Characterization by Dynamic Light Scattering (DLS). Polymeric micelles were formed via the quick heating procedure as described in the literature.27 In brief, the polymers were dissolved overnight at a concentration of 1 mg/mL in 20 mM HEPES buffer, pH 7.4. Subsequently, 1 mL of the polymer solution was transferred to a clean glass vial and characterized by dynamic light scattering (DLS) at 25 °C. To form micelles, the polymer solution was rapidly heated to 50 °C, and after 10 min of incubation the micelles were characterized by DLS at 37 °C. Afterward, the mixtures were cooled down again to 25 °C, and the same procedure to form micelles was repeated. The DLS equipment consisted of a Malvern CGS-3 multilangle goniometer with a JDS Uniphase He–Ne laser (λ = 632.8 nm, 22 mW output power) and a temperature controller (Malvern Instruments Ltd., Malvern, UK). Scattering of the micellar solutions was measured under an angle of 90°.

3. RESULTS AND DISCUSSION

3.1. Heterofunctional PEG Macrominitiator Synthesis and Characterization. The PEG macroinitiator was synthesized following a three-step synthesis route, starting with a Boc-protected NH₂-PEG-OH (Scheme 2). The first step consisted of a DCC-mediated ABCPA coupling to the free OH group, followed by deprotection of the Boc-protected amine groups and finally end-group functionalization with an ATRP initiator. Boc-NH-PEG₅₀₀-OH was commercially obtained, and as expected, no free primary amines could be detected with a TNBSA assay (Table 1). In addition, 1H NMR analysis displayed the characteristic peaks of the Boc-methyl protons at 1.4 ppm, and after addition of TFA, a number-average molecular weight (Mₙ) of 5.01 kDa was determined in agreement with the Mₙ obtained by GPC of 5.5 kDa. In addition, GPC analysis showed a small impurity (2.5%) of high molecular weight PEG in the starting compound.

The synthesis of the heterofunctional PEG macroinitiator started with the coupling of the azoinitiator to the amine-protected PEG by a DCC-mediated esterification between the carboxylic acid groups of ABCPA and the hydroxyl groups of PEG (Scheme 2, step 1). 1H NMR analysis showed the appearance of characteristic peaks corresponding to the CH₂ and CH₃ groups of ABCPA (Figure S1), indicating successful coupling of ABCPA to PEG. GPC analysis showed a major peak at 10 kDa corresponding to the molecular weight of the desired PEG macroinitiator (Figure 1). Overall, 84% of the final product was the desired bifunctional initiator, which corresponds to the typical yield of DCC-mediated esterification.

*The molecular weight (\(M_n\)) and the polydispersity index (PDI) were determined with GPC. The amount of free amines was determined with a TNBSA assay.*

reactions.\(^{34,28,29}\) The peak at 5 kDa in the GPC chromatogram is a result of a bimodal molecular weight distribution for the obtained product, which can be ascribed to a mixture of bifunctionalized PEG\(_2\)-ABCPA (10 kDa) and monofunctionalized PEG-ABCPA and/or unreacted PEG (5 kDa). The amount of unreacted PEG was determined by \(^1\)H NMR by the addition of TAC to the sample. \(^1\)H NMR analysis indicated that 11% unreacted Boc-NH-PEG\(_{5000}\)-OH was present. GPC showed the presence of 16% of the 5 kDa compound, meaning that the final product contained 5% monofunctionalized Boc-NH-PEG\(_{5000}\)-ABCPA. Separation of the 10 and 5 kDa PEG products by commonly used separation techniques, which are based on differences in molecular weight, is rather difficult. For example, to achieve preparative chromatography conditions, a large column would be needed to prevent overloading of the column, resulting in a low-resolution separation. Such large columns would be both impractical to work with and very expensive. In addition, although a dialysis membrane with a 10 kDa cutoff was used, traces of the 5 kDa PEG products were still visible in the GPC chromatogram, indicating that removal of these molecules via dialysis was not efficient.

The next step involved the removal of the Boc group with TFA (Scheme 2, step 2), and \(^1\)H NMR analysis showed the complete disappearance of the proton signal of the Boc group at \(\delta = 1.4\) ppm (Figure S2). In addition, almost full recovery of the free primary amines was found with the TNBSA assay (Table 1), and no changes in the GPC chromatogram were observed. The final step of the synthesis was the functionalization of (NH\(_2\)-PEG\(_{5000}\))\(_2\)-ABCPA with \(\alpha\)-bromoisobutyryl bromide to obtain a bifunctional ATRP initiator (Scheme 2, step 3). Results from both the \(^1\)H NMR analysis and the TNBSA assay indicated a nearly complete Br-functionalization on the PEG macroinitiator. The \(^1\)H NMR spectrum showed a sharp peak at \(\delta = 1.94\) ppm, which corresponds to the protons of the methyl groups of bromoisobutyryl (Figure S3). Comparing the integral of this peak with the integral of the peak at \(\delta = 3.8-3.5\) ppm (PEG) showed 98% Br-functionalization. In addition, results from the TNBSA assay showed the presence of 5% free primary amines, indicating that the final product contained 95% Br-functionalization.

3.2. ABC Triblock Copolymers Synthesis and Characterization. The first polymerization step involved the synthesis of the A block by ATRP, yielding an ABBA polymer. The azoinitiator remains intact during this polymerization step because ATRP reactions can be performed at low temperatures (reactions were performed on ice). After purification, the obtained ABBA polymer was used to synthesize the final block by free radical polymerization. The reaction mixture was heated to 70 °C, at which ABCPA decomposes and generates radicals to start polymerization of the final block. By employing this orthogonal synthesis route, linear ABC triblock copolymers can be polymerized in a two-step process without the requirement of protection of initiating sites. Because of the combination of two types of polymerization, a wide range of monomers can be included, yielding different kinds of polymer compositions. To illustrate the versatility of the heterofunctional PEG macroinitiator, ABC triblock copolymers with different block compositions were synthesized (Table 2). The polymer names are abbreviated according to the block composition, in which the first letter corresponds to the monomer used for the A block, the second letter to the B block, and the third letter to the C block. Three types of monomers with different properties were used for this study: DMAEMA, NIPAM, and HEA. All polymers were characterized by \(^1\)H NMR (Figures S4–S8) and GPC to determine the \(M_n\) of the polymers and the average lengths of each functional block.

In the first step, NIPAM was polymerized by ATRP, and the corresponding ABBA polymers (PNIPAM-PEG-PEG-PNI-PAM, abbreviated by NPPN) were obtained with a typical monomer conversion of 90% and a typical yield of 85% (Table 3). In addition, GPC analysis confirmed the formation of the ABBA polymer since the peak of the PEG macroinitiator (14 min, 10 kDa) was almost completely shifted to a lower retention time, corresponding to a higher \(M_n\) of the polymer product (Figure 2). Small traces of the PEG macroinitiator were visible in the GPC chromatogram, which corresponds to
the small fraction of nonfunctionalized PEG macroinitiator. The relative peak area (%) of the GPC peaks at 14 and 15 min (corresponding to the unreacted 10 and 5 kDa PEG macroinitiator, respectively) was 4% for each. In conclusion, the end product contained 92% of the desired ABBA polymer. The $M_n$ obtained by GPC was higher compared to the $M_n$ obtained by 1H NMR analysis, which has been reported in the literature before for NIPAM-based polymers. 33 Besides NIPAM, HEA was also polymerized by ATRP to form ABBA polymers (PHEA-PEG-PEG-PHEA, abbreviated by HPPH), and similar results were obtained, with the exception that the monomer yield was slightly lower (65%). After polymerization of the A block, the polymers were extensively dialyzed to remove the copper catalyst to prevent further ATRP upon addition of the second type of monomer.

In the second polymerization step, either DMAEMA or HEA was polymerized by FRP to obtain the final ABC triblock copolymers (Table 4). One of the advantages includes the widespread use of FRP and thus the possibility to choose a wide range of monomers suitable for polymerization. The PDI of the ABC triblock copolymers was between 1.8 and 2.5, which is similar to other triblock polymers reported in the literature.34,35 Typically, a monomer conversion of 60—70% was determined by 1H NMR, which can be expected for this

Table 2. Composition of Three Different ABC Triblock Copolymers Synthesized Using the Heterofunctional PEG Macroinitiator

| name   | polymer block composition | A       | B       | C       |
|--------|---------------------------|---------|---------|---------|
| NPD    | NIPAM (thermosensitive)   | PEG (hydrophilic) | DMAEMA (pH-sensitive) |
| NPH    | NIPAM (thermosensitive)   | PEG (hydrophilic) | HEA (hydrophilic) |
| HPD    | HEA (hydrophilic)         | PEG (hydrophilic) | DMAEMA (pH-sensitive) |

N-Isopropylacrylamide (NIPAM) was used to introduce a thermosensitive block in the polymer, 2-(dimethylamino)ethyl methacrylate (DMAEMA) was used to introduce pH-sensitive properties, and 2-hydroxyethyl acrylate (HEA) was used as non-charged hydrophilic monomer.

$^a$Either NIPAM was used to obtain PNIPAM-PEG-PEG-PNIPAM polymers (abbreviated by NPPN) or HEA to obtain PHEA-PEG-PEG-PHEA polymers (abbreviated by HPPH). $^b$Determined by 1H NMR. $^c$Determined by GPC.
The PDI values were comparable with those observed for the ABBA polymer. Indeed, a lower role in the observed hydrodynamic volume of the polymers. In addition, a lower value was observed for these two polymer batches. In addition, a lower value was observed for the ABBA polymer resulting into two ABC polymer blocks for materials in biomedical and pharmaceutical applications. The CPs of the thermosensitive polymers synthesized in this study were 33−34 °C (Table S10), as expected for these block copolymers.33,42 As a proof-of-principle, the self-assembly behavior of these thermosensitive polymers into well-defined macromolecular micellar structures was demonstrated by DLS (Table S5) in HEPES buffer pH 7.4.

After the micelles were formed (first time heating), the mixtures were cooled down again to 25 °C, and the same procedure to form micelles was repeated (second time heating).

At 25 °C, below the CP of the polymers, no particles were detected, indicating complete solubilization of free polymers. However, heating of the polymer solutions above the CP resulted in micellar structures with a size between 73 and 117 nm and a low PDI (0.06−0.17). These results are similar to other thermosensitive polymeric micelles based on NIPAM reported in the literature.24,43,44 The different compositions and M_n’s of the polymer batches led to slight differences in size of the micelles, with the polymer with lowest M_n (NPH, 39 kDa), resulting in the smallest micellar structure (73 ± 7 nm). The reversibility of the thermosensitive behavior was shown by the complete disappearance of the micelles after cooling down the mixture to 25 °C. In addition, when the heating procedure was repeated, micelles with the same size and PDI were obtained as before cooling down. These data support that functional polymers with well-defined properties, such as self-assembly behavior upon a trigger-like change in temperature, can be synthesized with the presented PEG macroinitiator.
4. CONCLUSION

This study shows the successful synthesis of a heterofunctional PEG macroinitiator containing both an azoinitiator and an ATRP initiator. Well-defined polymeric products are obtained using a combination of the living polymerization technique ATRP and classical free radical polymerization. The use of this novel heterofunctional PEG macroinitiator allows the synthesis of high-precision ABC copolymers, having a PEG midblock, in an elegant way. In addition, the combination of two types of polymerization techniques enabled the incorporation of a wide range of monomers into the polymer design. Multiple functionalities were combined in a single polymer chain, including pH-sensitive and thermosensitive properties and functional sites for postmodification reactions. This synthesis approach can further contribute to the design of dual-stimuli responsive polymers with tailorable block compositions and polymer topologies. Different kinds of self-assembled morphologies, depending on specific block properties, make these linear ABC triblock copolymers highly attractive for applications in nanotechnology.
