Introduction

Aluminosilicate zeolites with their uniform molecular-sized pores, high surface acidity, and large number of active sites have been extensively applied as molecular sieves, ion exchangers, and solid acid catalysts in industrial catalytic processes since the last century. They are usually prepared from alkoxide precursors under hydrothermal conditions by so-called molecular templating wherein a cationic organic species acts as a template for the formation of ordered pores and channels. This approach generates highly ordered microporous materials whose pore diameters are controlled by the size of the molecular templates. The pore sizes of zeolites are therefore below 15 Å and typically 4-10 Å. However, the conversion or adsorption of bulky organic molecules requires large pore channels (>2 nm), which has not been achieved in stable microporous zeolites. A synthetic challenge in this context is the disparate hydrolysis rates of Si and Al alkoxides which lead to homogeneous aluminosilicate xerogels containing Si–O–Al linkages through dimethylacetamide elimination. The addition of Pluronic P123 and F127 templates provides stiff gels that are, after calcination at 500 °C, converted to stable mesoporous xerogels with a high surface area (>600 m² g⁻¹) and wormhole-type pores (d = 5.9 nm). The xerogels exhibit high catalytic activity in aminolysis of styrene oxide (82% conversion) with the turnover frequency up to 100.

A novel non-hydrolytic sol–gel (NHSG) synthesis of mesoporous aluminosilicate xerogels is presented. The polycondensation between silicon acetate, Si(OAc)₄, and tris(dimethylamido)alane, Al(NMe₂)₃, leads to homogeneous aluminosilicate xerogels containing Si–O–Al linkages through dimethylacetamide elimination. The addition of Pluronic P123 and F127 templates provides stiff gels that are, after calcination at 500 °C, converted to stable mesoporous xerogels with a high surface area (>600 m² g⁻¹) and wormhole-type pores (d = 5.9 nm). The xerogels exhibit high catalytic activity in aminolysis of styrene oxide (82% conversion) with the turnover frequency up to 100.

mesoporous aluminosilicate catalysts. The assembly of ZSM-5, beta, TS-1, and FAU zeolite seeds was achieved with the use of structure-directing agents, such as cetyltrimethyl ammonium bromide (CTAB) or Pluronic P123. A so-called coated route approach using a dilute clear solution of primary zeolite units was employed to synthesize ultrastratish mesoporous aluminosilicate molecular siores. This method produces a new type of nanocrystalline zeolitic material with mesopore walls formed by a templated solid-state secondary crystallization of zeolites into walls of SBA-15.

Recently, Liu has obtained Al-rich mesoporous aluminosilicates with improved hydrothermal stability by assembling zeolite Y and beta precursors in the walls of mesopores. For example, the retaining ratio of the total surface area was 33% after hydrothermal treatment in 100% water vapor at 800 °C for 15 h. This group also reported a pH-adjusting method based on the assembly of beta zeolite. An approach recently published was employed to synthesize ultrastable mesoporous aluminosilicate gels.

The methods and procedures mentioned above all involve hydrolytic reactions. Aluminosilicates can also be successfully prepared by non-hydrolytic routes. With these methods, it is possible to overcome the problems of different hydrolysis rates and subsequent phase separation. These techniques allow reaction control on atomic scale and homogeneous dispersions of silicon and aluminum atoms in the gel network may be achieved. One type of non-hydrolytic sol–gel (NHSG) reaction is alkylhalogenide elimination. In this method, condensations between SiCl4, AlCl3, Al(OiPr)3, and Si(OiPr)4 in ethers or CH2Cl2 provide monolithic homogeneous aluminosilicate gels.

Non-hydrolytic sol–gel technique has also been applied to the preparation of highly active mesoporous metathesis catalysts MoO3–SiO2–Al2O3 and ReO3–SiO2–Al2O3. Mullite precursor gel synthesis was described from AlCl3 and TEOS in Et2O and CCl4 in an autoclave at 110 °C.

Catalytic efficiency of aluminosilicates was determined by a variety of test reactions. Kim reported Friedel–Crafts acylation of bulky aromatic compounds in MFI zeolite nanosponge, Neves used mesoporous aluminosilicates with acid sites for conversion of furfuryl alcohol to ethyl levulinate and Robinson described the alcoholyis and aminolysis of styrene oxide promoted by mesoporous aluminosilicate catalysts.

Non-hydrolytic alkylhalogenide elimination.

Experimental

General procedures

All manipulations were performed in dry nitrogen using Schlenk techniques or in an M. Braun drybox with both H2O and O2 levels below 1 ppm. Al(NMe2)3 is highly flammable and reacts violently with water, liberating flammable gases. It must be handled under dry inert gas at all times.

Chemicals, such as Pluronic P123 (EO20PO7EO20 Mw = 5845 g mol−1), Pluronic F127 (EO100PO65EO100 Mw = 12 600 g mol−1), tris(dimethylamido)aluminium Al[NMe2]3 (99%), styrene oxide (97%), aniline (97%), methanol, and nonane, were purchased from Sigma-Aldrich. Si(OAc)4, Si2O(OAc)6, Me3SiOAc, and Si2(CH2)3(OAc)6 were synthesized according to the published procedures. Toluene, methanol, and isopropanol were dried by standard methods and distilled before use. Pluronic P123 and F127 were dried under vacuum at 60 °C, dissolved in dry toluene, and stored as 20.17 and 19.61 wt% solutions, respectively.

Characterization

IR spectra were recorded on a Bruker Tensor 27 FTIR spectrometer from KBr pellets or on a Bruker Alpha-Platinum ATR system. GC-MS measurements were performed on a mass spectrometer TSQ Quantum XLS coupled with a gas chromatograph Trace GC Ultra by Thermo Scientific. The gas chromatograph was equipped with a TS-QGC column (length 15 m, diameter 0.25 mm, film thickness 0.25 μm) using a temperature program: 50 °C (0 min), 5 °C min−1 to 80 °C, 15 °C min−1 ramp to 120 °C, 35 °C min−1 ramp to 200 °C, held at 200 °C for 0.5 min. Split injection mode was used with the injector, interface, and detector temperatures all set to 200 °C. The column pressure was 31.5 kPa and the ionization energy was 70 eV. DIP MS measurements were performed with the temperature program 30 °C for 30 s, 50 °C min−1 30–450 °C, and held at this temperature for 1 min; the ionization energy was 44 eV. For liquid phase 1H and 13C NMR measurements, a Bruker Avance II DRX 300 MHz spectrometer was used. The spectra were referenced to the residual proton or carbon resonances of benzene-d6 (7.15 and 128.0 ppm) and CDCl3 (7.20 and 77.0 ppm). Solid state NMR spectra were measured on a Bruker Avance III 700 MHz spectrometer with a MAS DVT 700S4 BL4 N-

Scheme 1 Non-hydrolytic alkylhalogenide elimination.
Dectris LTS scattering curves were analyzed by ATSAS so adsorption under vacuum (1 h, 115 °C) calcined xerogels. Xerogels (2 g) were degassed at 100 °C for at least 3 h until the outgas rate was less than 0.4 Pa min⁻¹. The adsorption−desorption isotherms were measured for each sample at least three times. The specific surface areas (SA), total pore volumes (Vp at p/p0 = 0.98) and average pore size (d) were determined by volumetric techniques⁴¹,⁴² and analyzed by the multipoint BET method using at least five data points. The valid pressure ranges were established by the Rouquerol transform and equivalent BET surface areas were calculated. Pore size distributions were calculated by the NLDFT method from the adsorption branch of the isotherms with the use of a nitrogen-on-silica kernel. Thermal analysis (TG/DSC) was performed on a Netzsch STA 449C Jupiter apparatus in the stream of air (70 cm³ min⁻¹) with a temperature ramp of 5 °C min⁻¹ to 1000 °C, in a Pt crucible. Aluminium and silicon contents were determined by volumetric techniques and analyzed by the ICP optical emission spectrometer iCAP 6500 Duo (Thermo, UK) equipped with a solid-state generator with a frequency of 27.12 MHz and a maximum power input 1350 W. The measurements of Al were performed at 167.0, 308.2, and 309.2 nm. For Si analysis, wavelengths 212.4 and 251.6 nm were used. The measurements of Al were performed on an X’Pert PRO diffractometer equipped with a CuKα X-ray tube and a HTK 16 high-temperature chamber (Anton Paar, Graz, Austria) with a Pt holder. Samples were measured from 500 to 1250 °C in 50 °C increments. The sample was held during scanning at a constant temperature for 12 min. Nitrogen adsorption/desorption experiments were performed at 77 K on a Quantachrome Autosorb-1MP porosimeter. Prior to the measurements, the samples were degassed at 100 °C for at least 24 h until the outgas rate was less than 0.4 Pa min⁻¹. Adsorbed pyridine was exposed for 30 min to pyridine vapors under its autogenous pressure at 25 °C. After adsorption, samples were dried at room temperature under vacuum for 2 h. Adsorbed pyridine was characterized by the IR technique.

The single-crystal X-ray diffraction data were collected at 120 K using a Rigaku BioSAXS 1000 system at wavelength of 1.5408 Å with a PILATUS 100K detector, Dectris Lts. Scattering curves were analyzed by ATSAS software package. Studies of surface acidity were performed on air-calculated xerogels. Xerogels (ca. 50 mg) were dried before adsorption under vacuum (1 h, 115 °C). Then, the samples were exposed for 30 min to pyridine vapors under its autogenous pressure at 25 °C. After adsorption, samples were dried at room temperature under vacuum for 2 h. Adsorbed pyridine was characterized by the IR technique.

Condensation reaction between Me_2SiOAc and Al(NMe_2)_3

A model condensation reaction between Me_2SiOAc and Al(NMe_2)_3 (3 : 1) (Table 1) led to a molecular product (1) containing the N,N-dimethylacetimidic acid cation \([\text{Me(C)}\text{OHNMe}_2]\) and \([\text{Al(OSiMe}_3]_4\) anion (Fig. 1 and 1S†). Dime-thylacetamide, hexamethyldisiloxane, and small amount of dimethylamine were observed by GC-MS among the volatiles. The colorless crystalline product sublimed from the dark orange viscous mass on the walls of a Schlenk flask. These crystals (292 mg, 14%) were separated in glove box and analyzed by single crystal X-ray diffraction analysis.

Characterization of 1. ²⁷Al NMR (CDCl₃, ppm) δ 59 ppm (AlO₄).

EI-MS (m/z): 589 [Al₂(OSiMe₃)₆H⁺] (10%); 574 [Al₂(OSiMe₃)₅OSiMeH⁺] (100%); 485 [Al₂(OSiMe₃)₄OSiMeH⁺] (20%); 411 [Al₂(OSiMe₃)₃H⁺] (50%).

Catalytic reactions

Aminolysis and alcoholysis reactions of styrene oxide were performed in a 25 cm³ round-bottomed Schlenk flask connected to a N₂ source. Calcined (500 °C) aluminosilicate xerogels were degassed before the reactions under vacuum at 100 °C for 20 min. The reaction mixture consisted of catalyst (25 mg), dry toluene (5 cm³), styrene oxide (0.587 cm³, 5.00 mmol) and aniline (0.456 cm³, 5.00 mmol) or methanol (0.202 cm³, 5.00 mmol) in the case of aminolysis and alcoholysis, respectively. A blank reaction was performed without a catalyst. The reaction mixture was heated at 50 °C. Catalytic products were quantified by GC-MS and ¹H NMR spectroscopy after 10 min and 1 h.

The reaction proceeds with the formation of Si–O–Al network and release of dimethylacetamide which was confirmed by GC-MS (Fig. 2S†) and ¹H NMR analysis of volatiles separated from the reaction mixture. In the case of the reaction with excess Si(OAc)₄, a small amount of acetic acid was observed in GC-MS.

Hexaacetoxydisiloxane \((\text{AcO})₃\text{SiOSi(OAc)}₃\) (eqn (2)) and bis(triacetoxyisilyl)ethane \((\text{AcO})₂\text{Si}–(\text{CH}_2)₂–\text{Si(OAc)}₃\) (eqn (3)) were used for the modification of porosity and optimizing of the Si/Al ratio. Eqn (1) represents a complete condensation of functional groups to Si–O–Al network and quantitative elimination of dimethylacetamide. However, under experimental conditions, the condensation is incomplete (Scheme 2), and degree of condensation (DC) for the reaction without a template was 56%.

Reaction parameters are summarized in Table 1. Systems without the templates produced yellowish turbid gels which were dried under vacuum for 24 h to form yellow powders. With the use of templates, stiff and transparent yellow gels were obtained. These gels were dried to form yellow-orange rubbery or glassy products. Dried xerogels were afterwards calcined in a tube furnace at 500 °C for 3 h in air to remove the templates. The resulting yellowish powders possessed surface areas that were substantially improved and pore sizes corresponded to mesoporous region (see below).

To study the condensation, a model reaction between Me_2SiOAc and Al(NMe_2)_3 was carried out. It provided molecular ionic compound \([\text{Me(C)}\text{OHNMe}_2]\) \([\text{Al(OSiMe}_3]_4\) (1) (Fig. 1 and 1S†). Crystallographic details and IR spectrum of 1 are summarized in ESI (Table 1S, Fig. 3S†). A similar compound has been prepared by Chisholm from Me_3SiOAc and Al(NMe_2)_3. This product shows that condensation between acetoxo and dimethylamido groups takes place forming Si–O–Al bonds.

IR spectra of all dried products were recorded to identify Si–O–Al heterolinkages and also the residual organic groups. Fig. 2 illustrates IR spectra of non-templated and F127 templated dried samples synthesized by NHSG reactions. The absence of OH bands attests to the truly non-aqueous nature of the xerogel synthesis. Vibrational bands located at 1030, 1065, and 1005 cm⁻¹ are attributed to Si–O–Si and Si–O–Al bonds on the basis that introduction of Si–O–Al bonds in a SiO₂ matrix shifts the absorption maxima toward the lower wavenumbers. Besides the bonds mentioned above, vibrational bands of residual organic groups were observed as well. Dimethylamido groups give rise to vibrational bands at 1250–1270, 1370–1380, 1510–1520, and 2970–2980 cm⁻¹. Acetoxy moieties are characterized by the asymmetric and symmetric COO stretches at 1580–1590 and 1460–1470 cm⁻¹, respectively. The difference between symmetric and asymmetric carboxylate vibrational bands is 120–130 cm⁻¹ and according to Deacon–Phillips rules, this is indicative of the bidentate bridging mode on a metal center.

Pluronic templates P123 and F127 are represented by vibrational bands of C–O–C bonds at 1090–1105 cm⁻¹ and CH₃ at 2860–2880 cm⁻¹. The thermal behavior of the prepared products was studied by TG/DSC analysis in air. Residual masses are summarized in Table 1. These values are in an agreement with the calculated
residual masses corresponding to aluminosilicate $\text{Al}_x\text{Si}_y\text{O}_z$, where $x$, $y$, and $z$ represent moles of aluminium, silicon, and oxygen in precursors. For example, the TG residual mass of sample SiAlF2 (Table 1) is 29.94% while the calculated residual mass of aluminosilicate is 29.36%. TG curves (Fig. 4S†) of xerogels synthesized without the templates display mass losses in two steps. The first mass loss is observed between 50–225 °C (21–26%) and the second one between 230–500 °C (24%). These steps are connected with oxidation of residual dimethylamido and acetoxy moieties. In the case of templated samples the highest mass losses (52–56%) are observed between 200–450 °C. Xerogels with a lower content of Al show the highest mass loss between 125–400 °C (68–72%). A lower decomposition temperature than in the previous case could be explained by the oxidation of unreacted monodentate acetoxy groups bound to silicon. DSC curves of the templated samples (SiAlF2, SiAlF2) with 57–58 mol% of Al show exothermic peaks at 995 and 985 °C for the xerogel with F127 and P123 copolymer, respectively. This observation could be connected to crystallization of the mullite phase.46–48

Solid state NMR spectroscopy (Table 2) was employed for in-depth characterization of the aluminosilicate xerogel matrix. $^{13}$C CPMAS NMR spectrum of non-templated sample (SiAl1) displayed resonances of residual organic groups (Fig. 5S†). Resonances at 33.1, 35.0, and 37.8 ppm are attributed to dimethylamido groups while the acetoxy groups in bidentate and monodentate coordination are characterized by the CH$_3$ resonances at 22.0 and 24.1 ppm, respectively. The COO resonances of acetate groups in unidentate and bidentate mode were observed at 170.4 and 179.5 ppm, respectively. Similar

| SiAlF3      | −90             | 61            |
| SiAlF3-500  | −93             | 69            |
resonances of residual N(CH₃)₂ (34.1, 37.4 ppm), CH₃ (20.7, 23.1 ppm) and COO (169.8, 179.0 ppm) were observed also in the ¹³C CPMAS spectrum of the xerogel synthesized from bis(triacetoxysilyl)ethane (C₂SiAl). The ethylene (CH₂–CH₂) bridge is characterized by the signal at 7.5 ppm. In the ¹³C CPMAS NMR spectrum of F₁₂₇ templated xerogel (SiAlF₂, Fig. 5S†), the presence of residual organic moieties was observed as well. The N(CH₃)₂ groups are seen at 40.8 ppm and CH₃ of acetoxy species are displayed at 27.3 ppm. The carboxylate function features weak signals at 173.2 and 183.2 ppm. The template carbons are represented by chemical shifts at 21.0 (C₃H₃CHO), 74.1, 76.8, and 78.8 ppm (C₂H₂O and CH₃C₂HO).

The ²⁹Si CPMAS NMR spectrum of non-templated sample (SiAl₁) shows a broad signal with the maximum at ~89 ppm (Fig. 3). Compared to SiO₂ (~110 ppm)⁵⁶,⁵⁷ and Si(OAc)₄ (~96 ppm) a downfield shift is observed. This shift is caused by the presence of Si–O–Al linkages in the xerogel network.⁵⁸–⁵⁹ ²⁹Si CPMAS NMR spectrum of the sample C₂SiAl with ethylene (CH₂–CH₂) bridges displays a broad signal with the maximum at ~54 ppm (Fig. 3). ²⁹Si CPMAS NMR data of templated samples displays a broad signal at ~87 ppm assigned to Si(Osi)(OAl)₃ species (Fig. 3).⁶⁰,⁶¹ Similar resonances were observed after calcination at 500 °C of these templated samples (Fig. 4). The resonance at ~90 ppm in ²⁹Si CPMAS NMR corresponds to Si(Osi)(OAl)₃ species (Fig. 3). In the case of templated samples with a lower Al content (SiAlF₁), ²⁹Si CPMAS displays a signal with maximum at ~106 ppm and a shoulder at ~97 ppm. This shift could be caused by the formation of Si–O–Si bonds because of excess Si(OAc)₄ (Fig. 3). Comparison of ²⁹Si CPMAS NMR spectra before and after calcinations for the templated samples SiAlF₁, 2, 3 indicates there are not major differences (Fig. 4).

²⁷Al NMR spectra of dried xerogels provide information about the coordination number of Al atoms in the aluminosilicate network. ²⁷Al spectra of dried non-templated xerogels (SiAl₁, C₂SiAl) illustrate three signals attributed to 4-coordinated (Al⁴⁺, 53 ppm), 5-coordinated (Al⁵⁺, 28 ppm) and 6-coordinated (Al⁶⁺, 0 ppm) Al⁵⁺ (Fig. 6S†). ²⁷Al NMR spectra of calcined templated samples (SiAlF₂, 3) show also the resonances for Al⁴⁺ (58 ppm), Al⁵⁺ (31 ppm), and Al⁶⁺ (2 ppm) atoms in the framework (Fig. 6S†). No significant change in the ²⁷Al NMR spectra of calcined templated xerogels was observed and Al signals were found at 62 ppm (Al⁴⁺), 33 ppm (Al⁵⁺), and 4 ppm (Al⁶⁺).⁶² ²⁷Al NMR spectrum of the sample SiAlF₁ (lower Al content) displays signals for Al⁴⁺ at 54 ppm and for Al⁵⁺ at ~2 and ~4 ppm. After calcination of this sample, the resonances at 61 ppm (Al⁴⁺), 32 ppm (Al⁵⁺), and 2 ppm (Al⁶⁺) were observed (Fig. 5). A mixture of xerogel signals are summarized in Table 2. From these NMR data we can conclude, that the calcined xerogels still contain Si–O–Al bonds and no phase separation takes place during the calcination. The ²⁷Al NMR and EPR observations made by Chen et al. show association of five-coordinated aluminum atoms to Lewis acid sites.⁶³ Hence, the effect of different aluminum coordination and their acid–base properties...
on the catalytic activity is a very interesting subject. $^{27}\text{Al}$ MAS spectrum of hydrothermally treated sample SiAlF2-500H shows intensity decrease of signal corresponding to 5-coordinated Al while the signal of 6-coordinated Al atoms increased (Fig. 7S†). This change is caused by coordination of water and –OH groups.

Solid state MAS NMR spectra of the samples synthesized with the P123 template are similar and thus are not shown here.

A very important feature of these aluminosilicate xerogels is their porosity. High surface area materials with mesopores provide better catalytic efficiency for the processing of bulky organic molecules. We investigated the N$_2$ adsorption/desorption isotherms of the non-templated and templated samples (Table 3). The results show that xerogels synthesized without copolymer templates exhibit high surface areas after drying and feature the type-II isotherms (Fig. 6). Equivalent BET surface areas of xerogels prepared from Si(OAc)$_4$ (SiAl1) and from the ethylene bridged acetoxysilane (C2SiAl, Fig. 8S†) were 607 and 517 m$^2$ g$^{-1}$, respectively. However the pore diameters correspond to micropores in both materials. After calcination of the C2SiAl sample at 200 °C, surface area decreased considerably to 36 m$^2$ g$^{-1}$. This change can be explained by the framework collapse while the ethylene bridging groups are oxidized.

Interestingly, according to the NLDFT method, the pore diameter increased and shifted to the mesopore region (4.8 nm).

An improvement in morphological properties is achieved through the use of Pluronic templates (Table 3). With this approach, framework collapse during heat treatment is avoided and high surface areas are achieved after calcination at 500 °C. The shape of isotherms corresponds to type IV with the H2 hysteresis consistent with significant mesopore content and narrower pore size distributions (Fig. 6 and 9S†).61 Calcined xerogel SiAlP2-500 synthesized with the P123 template containing 59.3 mol% of Al exhibits surface area of 591 m$^2$ g$^{-1}$ and the pore volume 0.53 cm$^3$ g$^{-1}$. If (AcO)$_3$SiOSi(OAc)$_3$ is used as the silicon precursor, the surface area increases to 627 m$^2$ g$^{-1}$. This change can be caused by better crosslinking due to a higher number of functional groups. Pore diameters of these calcined samples calculated by the NLDFT method are between 4.9 and 5.9 nm (Table 3). We observed that with increasing Al content the surface areas and pore volumes increased as well. Pore diameters do not change with different Si/Al ratios for P123 but...
increased for F127. For classification of thermal stability, we calcined the sample SiAlF2 at 700 °C for 3 h and remeasured N2 adsorption isotherms (Fig. 7). Its surface area reached 424 m² g⁻¹ (Vtot = 0.41 cm³ g⁻¹) which is about 53 m² g⁻¹ lower than in SiAlF2-500 and the pore volume and diameter decreased (Fig. 8, Table 3) and the distribution is narrower. To investigate hydrothermal stability, the sample SiAlF2-500 was exposed to boiling water for 24 h (Fig. 7). The surface area after this test was reduced to 166 m² g⁻¹ and pore volume to 0.28 cm³ g⁻¹. The pore size distribution maximum moved to 6.1 nm and the mesoporous character was preserved (Fig. 8). Compared to this sample, the hydrothermally treated sample (SiAlF3-500H) synthesized with (AcO)3SiOSi(OAc)3 exhibits also loss of surface area and pore volume while pore diameter increased (Table 3, Fig. 11S†).

SAXS measurements of the calcined samples SiAlP2-500 and SiAlF2-500 synthesized with the P123 and F127, respectively, show a weak scattering maximum at 0.42 Å⁻¹ (0.06 Å⁻¹) (Fig. 9). This behavior points to the mesoscopic ordering with the uniform pore channels in the xerogel.

The morphology of calcined mesoporous xerogels was studied by the TEM technique. The micrographs illustrate “wormhole” structure of pores (Fig. 10).

The surface acidity of the calcined xerogels was studied by pyridine adsorption. The IR spectra of the pyridine-treated samples (Fig. 11) display weak absorption bands at 1450, 1492, 1548, 1599, 1625, and 1639 cm⁻¹. The bands corresponding to Lewis acid sites (LPy) are present at 1450 and 1625 cm⁻¹.61,64 Both Lewis and Bronsted acid sites are attributed to a vibrational band at 1492 cm⁻¹. Bronsted acidic sites (BPy) are characterized by the absorption bands at 1548 and 1639 cm⁻¹.64 Pyridine adsorbed by hydrogen bonds (HPy) of ≡Si–OH moieties can be assigned to the vibrational band at 1599 cm⁻¹.61 These findings show that synthesized aluminosilicate xerogels exhibit surface acidity of both Lewis and Bronsted type.

High-temperature powder X-ray diffraction (HT PXRD) was used to determine the crystal phases that arise during calcination (Fig. 12S†). It was found that templated samples remain amorphous up to high temperatures and then crystallize to mullite (PDF 82-1237).65-67 The xerogels SiAlP2 and SiAlF2 are...
amorphous up to 950 °C before the diffraction lines of mullite are observed at 1000 °C (Fig. 12S). These findings correspond to exothermic effects in DSC analysis (995 and 985 °C). In the case of xerogels with a lower content of Al, diffraction evidence for mullite appeared at 1050 °C. Besides the mullite phase, crystalline SiO₂ (crystobalite PDF 85-0621) at 1100 °C was observed as well. The presence of cristobalite could be explained by the excess of Si(OAc)₄ in the starting mixture which reaches the crystallization temperature of SiO₂ at 1100 °C. These nanoporous aluminosilicates can be transformed to homogeneous mullite phase.

Catalytic studies

Catalytic activities of the synthesized xerogels were tested in two types of model reactions (Fig. 13S and 14S). At first, aminolysis of styrene oxide with aniline was investigated with the calcined aluminosilicate xerogel as a catalyst. The second model reaction was alcoholysis of styrene oxide with methanol. Catalytic yields for aminolysis are summarized in Table 4. The blank reaction without a catalyst was performed as well and no product was obtained after 4 h. We observed that our calcined mesoporous xerogels are efficient catalysts for aminolysis reaction of epoxides. The ¹H NMR spectra of the reaction mixture (in C₆D₆) display resonances attributed to two products: 2-phenyl-2-(phenylamino)ethanol (Ia) and 1-phenyl-2-(phenylamino)ethanol (IIa) (Fig. 13S and 15S). These products were also confirmed by the GC-MS technique. Catalytic yields were analyzed after 10 and 60 minutes. The highest conversion was observed with the catalyst SiAlF₁-500 (82% after 1 hour). However, high catalytic efficiencies (up to 80%) were reached in all cases (Table 4). Catalyst with a high content of Al exhibits a lower catalytic activity which could be caused by the presence of larger alumina clusters. Xerogels synthesized with (AcO)₃SiOSi(OAc)₃ provide higher homogeneity and better dispersion of Al in framework and furthermore a higher catalytic activity. We also investigated recycling the catalysts in the second reaction run. The styrene oxide conversion with 7 mg of reused xerogel (SiAlF₃-500) reached 21% after 1 h which represents nearly the same activity (TOF = 20) as the fresh catalyst. A report describing aluminosilicates as catalysts for aminolysis was published by Robinson. These nanoporous catalysts are prepared by conventional hydrolytic sol–gel process from TEOS and aluminium nitrate nonahydrate in the presence of cetyltrimethylammonium bromide. The comparison between these catalysts and our mesoporous aluminosilicates is presented in Table 5.

In the case of styrene oxide alcoholysis, our catalysts exhibit a lower efficiency than in aminolysis reactions. Catalytic products confirmed by GC-MS and ¹H NMR were (Fig. 15S and 16S) (1,2-dimethoxyethyl)-benzene (IIb) and phenylacetaldehyde (IIIb) (Fig. 14S, Table 6). Catalyst SiAlF₁-500 exhibits 28 and 44%

| AlKIT-5(10)[28] | 10    | r. t.           | 6        | 50     | 95             | 95 : 5                     |
conversion of styrene oxide after 2 and 5 h, respectively. Selectivity for (1,2-dimethoxyethyl)-benzene after 5 h reached 54%.

We also performed a catalytic reaction with the catalyst SiAlF1-500 where no methanol was used. In this case, phenylacetaldehyde was observed as the only product and the catalytic yield after 1 h was 35%. A leaching test confirmed that no Al was released into the solution. Only 0.3% of the total aluminium amount in catalyst was found in the filtrate.

Conclusions

The non-hydrolytic sol–gel (NHSG) reactions based on acetaldehyde elimination described here provide a very effective route to homogeneous aluminosilicate xerogels with high Al loading. This one pot reaction proceeds as polycondensation between acetoxysilanes and aluminium(III) dimethylamid and leads to the formation of Al–O–Si networks. In all cases, N,N-dimethylacetamide was confirmed as the only reaction byproduct attesting to the absence of homocondensation reactions. Al–O–Si bonds were identified by IR spectroscopy and $^{29}$Si and $^{27}$Al MAS NMR spectroscopy. We observed 4-, 5-, and 6-coordinated Al atoms in the frameworks of both dried and calcined xerogels. These materials exhibit high surface areas (up to 607 m$^2$ g$^{-1}$) but are microporous. Calcination causes framework collapse and samples lose porosity. With the use of block copolymer templates such as Pluronic P123 and F127, homogeneous, stiff gels were obtained. After calcination at 500 and 700 °C mesoporous aluminosilicate materials with high surface areas ranging from 380 to 627 m$^2$ g$^{-1}$ with the pore diameters 4.9 (P123) and 5.9 (F127) nm were obtained. After hydrothermal treatment, the surface area decreased but mesoporous character was preserved. Calcined xerogels were investigated as catalysts for the aminolysis and alcoholysis of styrene oxide. The presence of catalytic active acidic sites (Lewis, Brønsted) was determined by pyridine adsorption. All xerogels exhibit good catalytic activity. Especially in the aminolysis model reaction, very high conversions (69–82%) were observed.
