Our understanding of localization in the integer quantum Hall effect is informed by a combination of semi-classical models and percolation theory. Motivated by the effect of correlations on classical percolation we study numerically electron localization in the lowest Landau level in the presence of a power-law correlated disorder potential. Careful comparisons between classical and quantum dynamics suggest that the extended Harris criterion is applicable in the quantum case. This leads to a prediction of new localization quantum critical points in integer quantum Hall systems with power-law correlated disorder potentials. We demonstrate the stability of these critical points to addition of competing short-range disorder potentials, and discuss possible experimental realizations.

I. INTRODUCTION

One of the hallmarks of the quantum Hall effect is the appearance of plateaus in the Hall resistance of a two-dimensional electron gas as a function of applied magnetic field. Transitions between plateaus have been associated with a quantum critical point. This critical point corresponds to a localization-delocalization transition for the electron’s wave-function. Unlike the Anderson metal-insulator transition here the transition is between two insulating states: an extended wave function emerges at a single value of the magnetic field corresponding to the center of a Landau band. Experiments and numerical simulations have revealed many important properties of this critical point, such as the value of the correlation length exponent, \( \nu_q \approx 2.3 \). Attempts at formulating an analytically tractable theory of the transition have by and large failed.

A very fruitful approach to unraveling the physics of plateau transitions has been the semi-classical description of electron dynamics in the lowest Landau level. Classically the electron’s motion can be described as a fast cyclotron rotation in the plane accompanied by a slow \( \mathbf{E} \times \mathbf{B} \) drift of the center of the circular orbit along lines of constant random potential, \( V(\mathbf{x}) = \text{const.} \). Quantum mechanics adds tunneling and interference to the mix.

The purpose of this work is to understand the relation between classical and quantum dynamics of electrons in the lowest Landau level, in the presence of a random potential. In particular we investigate the effect of the fractal geometry of the classical orbits on the critical properties of the quantum localization-delocalization transition, such as the value of \( \nu_q \). One of our main results is that we have identified a family of random potentials for which the classical electron orbits have continuously varying fractal properties, while the quantum critical point remains unchanged. These random potentials are characterized by decaying power-law correlations in space. When the decay of correlations is not too fast we find new quantum critical points which are the quantum analogs of correlated percolation.

Previously, a real-space renormalization group treatment of correlated quantum percolation appeared in Ref. 7. Preliminary results of our numerical approach were reported in Ref. 8. Here we provide a detailed account of the numerical methods used to study the effect of power-law correlated disorder potentials on the integer quantum Hall transition (IQHT), as well as theoretical arguments supporting them. We also describe new results on the stability of these quantum critical points to the presence of short-range correlated disorder. The stability analysis provides connections with experiments where these new quantum critical points might be observed.

The work presented here addresses two different aspects of the problem. On one side the motivation is provided by understanding the role of disorder in determining the transport properties of quantum Hall systems. On the other side, we are motivated by the possibility of extending correlated percolation results in the classical regime to the quantum regime.

A. Disorder and the quantum Hall effect

The role of disorder in the quantum Hall effect was recognized shortly after its discovery. From scaling theory it is known that electron wave-functions are localized by potential disorder in two-dimensions. This remains true in the presence of a strong perpendicular magnetic field for states in the tails of the Landau bands, and leads to the observed plateaus in the Hall resistance. Toward the center of a Landau band the localization length increases signaling the appearance of a delocalized state.
This results in the observed transition between plateaus in the Hall resistance and the peak in the longitudinal resistance.

The precise nature of the disordered potential experienced by electrons in quantum Hall systems remains poorly understood. The canonical picture (say, for GaAs heterostructures) is that ionized donors located between the two-dimensional electron gas and the sample surface are responsible for the random potential. Important experimental progress has come from scanning techniques which provide a map of the electrostatic potential seen by electrons in a semiconductor heterostructure. Interestingly enough the experiment measures random potential fluctuations that extend over distances that are more than an order of magnitude larger than the typical spacing between the impurities and the electron gas, suggesting that the potential might be longer ranged that previously thought. Scanning techniques and the ability to manipulate single atoms on surfaces also opens up the possibility of engineering the random potential so as to produce novel transport effects. For example, an enhancement of the conductivity (compared to the Drude value) of a two-dimensional electron gas was observed in Ref. 8 due to the presence a random magnetic field. In this case the random field was produced by a thin film of rough magnetic material brought in close proximity to the electron gas. The fluctuations of the field were inherited from the height fluctuations of the films surface.

Inspired by these experimental advances here we describe how power-law correlated disorder can lead to novel critical behavior of the electron gas in the integer quantum Hall setting. We also analyze the effect of competing disorders, which are necessarily present in semiconductor heterostructures, on the stability of these critical points.

B. Quantum percolation

The classical percolation problem provides one of the most intuitive examples of a critical point. Lattice sites are occupied with some probability $p$. Nearest neighboring sites which are occupied form clusters with a typical size $\xi$. As $p$ is tuned to its critical value $p_c$, which depends on the lattice type, the correlation length $\xi$ diverges as $\xi \sim |p_c - p|^{-\nu_c}$. $\nu_c$ is the correlation length exponent, and in two dimensions $\nu_c = 4/3$ independent of the lattice type.

An analogous picture has been put forward to describe the localization transition in the integer quantum Hall system. For a smooth random potential (one that varies little on the scale of the magnetic length) the electron wave-function is localized along the level lines. For random potential symmetric around $V = 0$ level lines away from the zero level are closed and have a typical size $\xi$ which is identified with the localization length. As the electron’s energy is tuned to the center of the Landau band the corresponding level line approaches $V = 0$ and $\xi$ diverges. If the random potential has short range correlations in space this is precisely the classical percolation problem and one would predict a localization length exponent $\nu_q = \nu_c = 4/3$.

Experiments that measure a localization length exponent in the integer quantum Hall system find $\nu_q \approx 2.3$, signaling a break-down of the simple percolation picture. The essential physics that has been left out is one of electron tunneling, which readily occurs at the saddle points of the random potential, as well as quantum interference. This was beautifully demonstrated by Chalker and Coddington who proposed a lattice model which takes into account these purely quantum effects, by describing electron dynamics as hopping from one saddle point to the next with scattering matrices associated with each saddle. The saddle points themselves occupy the vertices of a square lattice. Computer measurements of the localization exponent for this model yield values in agreement with the experimental results. Moreover, taking a classical limit of the network model, in which the scattering matrices become classical probabilities for the two possible outcomes of a scattering event at a vertex, leads to classical percolation and a localization length exponent of $4/3$. This provides an intriguing connection between the critical points of classical and quantum percolation. Here we investigate the nature of this connection when power-law correlations are introduced in the random potential. In the classical case it was shown that this can lead to new critical points if the power-law decay is not too fast. We show that a similar effect occurs for the quantum version of percolation provided by electron localization in the lowest Landau level.

The paper is organized as follows. In section II we discuss the physics of classical and quantum electron motion in a disordered potential in the presence of a strong magnetic field. We present scaling arguments that show how the value of the critical exponent $\nu$ can be extracted from the time dependent mean square displacement (classical motion) and the time dependent wave-packet spread (quantum motion). In section III we describe in detail the numerical methods used to obtain the value of $\nu$ in the classical and quantum setting. As evidence of the suitability of these methods, we present results for short-range correlated disorder potentials that are in good quantitative agreement with previous experimental and theoretical works. Section IV contains the numerical results obtained for classical and quantum electron motion in power-law correlated disorder potentials. In section V we propose a framework based on the classical Harris criterion and its extension that provides the theoretical support for our numerical results.

Finally, in section VI we present results on classical and quantum localization in the presence of competing short-range and power-law correlated disorders. In experiments, which we believe have a good chance of observing the newly discovered quantum critical points, both types of disordered potentials are present. The key question here is whether correlated quantum percolation
is stable to the addition of short-range correlated disorder.

II. CLASSICAL AND QUANTUM MOTION IN THE LOWEST LANDAU LEVEL

The methods and tools used to describe the localization-delocalization transition in the lowest Landau level (LLL) in the classical regime are considerably different from the ones used in the quantum regime. In this section, we review both approaches and present the arguments leading to the connection between the localization exponent \( \nu \) and electron dynamics.

A. Classical motion

The two-dimensional semi-classical motion of an electron in a disorder potential under a strong constant magnetic field (along the \( \hat{z} \)-axis), is described by the drift motion of the electron’s guiding center along equipotential lines:

\[
\frac{d r}{d t} = -eB \nabla V(r) \times \hat{z}; \tag{1}
\]

where \( r \) is the position vector for the guiding center in the \((x, y)\) plane. This equation is derived in the adiabatic approximation, i.e., under the assumption that the cyclotron radius \( \ell_c = v/\omega_c \) is much smaller than the typical distance over which the potential changes. Therefore, the localization-delocalization transition in the LLL in the classical regime, implies the study and characterization of the trajectories determined by this equation.

Eq. (1) was extensively studied in two different albeit related contexts. F. Evers used this equation in numerical studies of classical motion along the hulls of percolation clusters. He demonstrated interesting scaling behavior of the time-dependent density-density correlation function close to the percolation critical point.

Y. Gurarie et al.\(^1\) arrived at Eq. (1) from the classical limit of the Liouvillian equation of motion for electrons in the lowest Landau level of the integer quantum Hall regime. In both cases, the authors considered smooth random potentials with short-range correlations in space.

One goal of this work is to study numerically properties of closed trajectories determined by Eq. (1), where \( V(r) \) is power-law correlated in space. In particular, we focus on the scaling law, and its associated critical exponent \( \nu \), which describes how the size of a closed trajectory grows as the energy approaches the critical value determined by the \( V(r) = 0 \) equipotential.

To make explicit the connection between \( \nu \) and the dynamics of a particle moving in a two-dimensional random potential, let us briefly review the argument presented in Ref.\(^1\). For a fixed constant value of \( V(r) = V_0 \), there is a set of equipotentials associated with closed electron trajectories. These trajectories are the outer boundaries (hulls) of percolation clusters, with the occupation probability \( p \) of the percolation problem determined by \( V_0 \). In particular, the critical value of \( p_c = 1/2 \) corresponds to \( V_0 = 0 \) in the units chosen. Several studies\(^18,19,20\) have shown that the mean squared displacement between two points on a given trajectory \( \Delta r^2 \) (\( r \) is the position vector for the particle on the trajectory), when averaged over all trajectories for fixed \( V_0 \), follows a diffusive law:

\[
\langle \Delta r^2(t) \rangle_{V_0} = D t \quad (t \ll t^*). \tag{2}
\]

Here \( t^* \) is a characteristic time that depends on \( V_0 \).

Away from the percolation critical point particle trajectories are closed, and in the long-time limit the mean squared displacement reaches a constant value

\[
\langle \Delta r^2(t) \rangle_{V_0} = \xi^2 \quad (t \gg t^*), \tag{3}
\]

where \( \xi(V_0) \) is the localization length.

These considerations lead to a scaling form (at fixed \( V_0 \)) for the mean squared displacement

\[
\langle \Delta r^2(t) \rangle_{V_0} = D t f \left( \frac{Dt}{\xi^2} \right), \tag{4}
\]

where \( f \) is a scaling function. The classical result from percolation theory\(^2\) for the correlation length, \( \xi \propto |p - p_c|^{-\nu_c} \), leads to the expression \( \xi \propto V_0^{-\nu_c} \), which in turn implies

\[
\langle \Delta r^2(t) \rangle_{V_0} = D t f \left( \frac{D t}{V_0^{-2\nu_c}} \right). \tag{5}
\]

Finally, by averaging this equation over all values of \( V_0 \) one obtains the scaling relation

\[
\langle \Delta r^2(t) \rangle \sim t^\theta, \tag{6}
\]

where \( \theta = 1 - 1/2\nu_c \) is the anomalous diffusion exponent.

From simulations \( \langle \Delta r^2(t) \rangle \) can be computed which leads to a value for \( \theta \) and, via the scaling relation just derived, to a value for the localization length exponent \( \nu_c \) in the classical regime.

B. Quantum motion

One approach to study the localization-delocalization transition in disordered quantum systems is based on the different contributions that extended and localized electron wave-functions make to the frequency dependent electrical conductivity\(^21\). Localized states appear in the electrical conductivity through the retarded density-density Green’s function, a quantity that has an intuitive
interpretation when written in terms of wave-functions. When the electron is represented by a localized wave-packet at position \( r \) and time \( t = 0 \), the Green’s function gives the value of the wave-packet spread at time \( t \). Since this wave-packet describes the probability of finding the electron at a given position and time, its spread is a measure of the uncertainty on the electron’s position, and as such, an indicator of localization.

In most studies of localization, the Green’s function is calculated in the momentum-frequency domain and studied in detail in the limit of large momenta/small frequency. The purpose of this section is to show explicitly how the critical exponent \( \nu_q \) can be extracted from the Green’s function using instead the real time domain, as proposed by Sinova, Meden and Girvin. Within this approach, one studies the disorder averaged density-density correlation function projected onto the LLL, i.e., the focus is on the unconstrained spectral function. As pointed out in Ref. 12, the applicability of the method rests upon the assumption that delocalized states in the IQH transition are isolated from each other and located at the centers of the Landau bands. Thus, when the density-density correlation function is restricted to one Landau level (the lowest being considered for simplicity), the contribution of the (single) delocalized state in that level dominates the sum over states in the small \( (q, \omega) \) limit. Equivalently, the integral of the spectral function over all energies is dominated by the contribution from the critical energy in that limit.

For our purposes, the main advantage of this approach is that it clearly spells out a numerical scheme for studying the effect of power-law correlated disorder potentials on localization in the lowest Landau level.

In order to make connections with electron motion in the classical regime and also to fix the notation used in the rest of the paper, we review some of the main points of the approach. Consider 2d spinless electrons (the electron spin is fixed by the magnetic field and we assume that spin-flipping interactions are not allowed) in the \( x-y \) plane, under the combined effects of a magnetic field \( \mathbf{B} = B \hat{z} \), perpendicular to the plane and a random potential \( V(\mathbf{r}) \) due to the presence of impurities.

The electron-impurity interaction is given by:

\[
H = \sum_{k} V_{-k} \rho_{k},
\]

where \( \rho_{k} = e^{i \mathbf{k} \cdot \mathbf{r}} \) is the one-particle density operator and \( V_{k} \) is the Fourier transform of the disorder potential. At high enough magnetic fields (or low enough temperatures), the kinetic energy is quenched to the value of the lowest Landau band and the sum is reduced to a sum over states in the LLL. Let \( \tilde{H} \) and \( \tilde{\rho} \) be the Hamiltonian and one-particle density operator projected onto the LLL. Then,

\[
\tilde{H} = \sum_{k} V_{-k} \tilde{\rho}_{k},
\]

with the projected one-particle density operator taking the form:

\[
\tilde{\rho}_{k} = e^{-\frac{\epsilon_{c}^{2}}{2} k^2 / 4} e^{i \mathbf{k} \cdot \mathbf{C}} \tag{9}
\]

with \( \mathbf{C} \), the position vector for the guiding center of a one-particle orbit, defined as:

\[
C_{x} = x - \frac{c}{eB} \Pi_{y} \quad \text{and} \quad C_{y} = y + \frac{c}{eB} \Pi_{x}. \tag{10}
\]

Here \( \Pi = p + \frac{q}{e} \mathbf{A} \) and \((x, y)\) are the canonical momentum and position operators for one particle.

The formalism used to project the density operator \( \rho_{\mathbf{q}} = e^{-i \mathbf{q} \cdot \mathbf{r}} \) onto the LLL was developed in Refs. 25, 26. There it was shown that the commutation relation for the projected density operator obeys a closed algebra (the magnetic translation operator algebra):

\[
[\tilde{\rho}_{\mathbf{k}}, \tilde{\rho}_{\mathbf{q}}] = 2i \sin \left( \frac{\epsilon_{c}^{2}}{2} k \cdot q \right) e^{-\frac{\epsilon_{c}^{2}}{2} k \cdot \mathbf{q}} \rho_{k+\mathbf{q}}. \tag{11}
\]

with \( k \times q = (k \times q) \cdot \hat{z} \). This property implies that the equation of motion for the density operator

\[
i \hbar \frac{\partial}{\partial t} \tilde{\rho} = [\tilde{H}, \tilde{\rho}] \tag{12}
\]

is closed and can, in principle, be solved exactly.

Following the same line of argument, one can show that similar results hold also for the correlation function of the projected density operator:

\[
G(\mathbf{r}, t) = Tr (\tilde{\rho}(\mathbf{r}, t) \tilde{\rho}(0, 0)) \tag{13}
\]

note that the trace extends over states in the lowest Landau level only. The density-density correlation function \( G \) in \( \mathbf{k} \)-space satisfies the equation:

\[
i \hbar \frac{\partial}{\partial t} G(\mathbf{k}, t) = \sum_{\mathbf{q}} 2i \sin \left( \frac{\epsilon_{c}^{2}}{2} k \cdot q \right) V(\mathbf{k} - \mathbf{q}) \exp[-\frac{\epsilon_{c}^{2}}{2}(k^2 - k \cdot \mathbf{q})] G(\mathbf{q}, t) \tag{14}
\]

which follows from Eq. 11. This is a Schröedinger-like equation where the effective Hamiltonian is the Liouvillian matrix:

\[
\mathcal{L}_{\mathbf{kq}} = 2i \sin \left( \frac{\epsilon_{c}^{2}}{2} k \cdot q \right) V(\mathbf{k} - \mathbf{q}) \exp[-\frac{\epsilon_{c}^{2}}{2}(k^2 - k \cdot \mathbf{q})]. \tag{15}
\]

(The name Liouvillian is used because of the analogy with the Liouvillian operator in classical mechanics.)

An interesting feature of Eq. 15 is that for a fixed value of the magnetic field, the magnetic length \( \ell_{c} (\ell_{c}^2 = \epsilon_{c}^2 / 4) \)
\[
\frac{\hbar}{\epsilon B} = 1, \quad \text{Eq. 10}\]

gives \(\nu = 1/2\).

\[
\frac{\partial}{\partial t} G(r, t) = \epsilon_{ij} \partial_i V(r) \partial_j G(r, t). \quad (16)
\]

A solution of this equation is \(G(r, t) = \delta(r - r(t))\) where

\[
\frac{dr}{dt} = \nabla V(x, y) \times \hat{z}. \quad (17)
\]

In other words, Eq. 10 describes the classical motion of the electron’s guiding center along equipotentials of \(V(r)\).

As argued above, the Liouvillian driving the quantum dynamics of an electron in the LLL, contains information about localization and the value of the critical exponent \(\nu_q\). The following scaling argument provides a numerical algorithm for extracting the localization exponent from the time dependent projected density-density correlation function. (We would like to draw attention to a close analogy between the present argument and the ideas presented in Sec. II A.)

Let us start with Eq. (8), and assume that all eigenvalues and eigenstates, localized and delocalized, are known. Assume next that the disorder potential breaks completely the degeneracy of the LLL, and that there is only one extended state at energy \(E = 0\). We construct a wavepacket at time \(t = 0\) using only localized states with energies in the \(\Delta\) neighborhood \(E' \neq 0\), and then we let the wavepacket evolve in time. The state-vector corresponding to such wavepacket is:

\[
|\psi(E') (t) > = \sum_{i=E' - \Delta}^{E' + \Delta} c_i(t) |i > \quad (18)
\]

where \(|i >\) are eigenvectors of the Hamiltonian projected onto the LLL (see Eq. 8).

At very short times, the spread of the wavepacket as a function of time is ballistic (see Appendix for derivation). However, after some crossover time and before the localization length corresponding to the energy \(E'\) is reached, the spread of the wavepacket averaged over disorder realizations is diffusive:

\[
< \Delta r^2 (t) >_{E'} = D t f\left(\frac{D t}{\xi^2 (E')}\right), \quad (21)
\]

where \(f'\) is the appropriate scaling function. Now if a localized wavepacket at time \(t = 0\) is constructed with all the eigenstates (including the lone delocalized state at the center of the LLL), its wave-vector can be written as:

\[
|\psi(t) > = \sum_{E'=-\infty}^{E'=0} |\psi(E') (t) > . \quad (22)
\]

Using this decomposition the dispersion of \(|\psi(t) >\) can be expressed as

\[
< \Delta r^2 (t) > \approx \int_{E'=-\infty}^{0} dE' \lesssim < \Delta r^2 (t) >_{E'} \ g(E') , \quad (23)
\]

where \(g(E')\) is the density of states; the contribution of the cross terms can be neglected assuming that the extended state is non-degenerate. Specifically, it can be shown that the cross terms are a correction to the leading behavior if there is only one extended state at the critical energy \((E = 0)\). Replacing \(< \Delta r^2 (t) >_{E'}\) by Eq. 21, using the fact that the density of states is non-singular and that \(\xi\) is related to \(E'\) by \(\xi (E') \sim (E')^{-\nu_q}\), we obtain:

\[
< \Delta r^2 (t) > = \int_{-\infty}^{0} dE' \ D t \ g(E') f'\left(\frac{D t}{E' - 2\nu_q}\right) \quad (24)
\]

Finally, an appropriate rescaling gives:

\[
< \Delta r^2 (t) > \approx t^\theta ; \quad \theta = 1 - 1/2\nu_q, \quad (25)
\]

and we conclude, as in the classical case, that the spread of the wavepacket is sub-diffusive with an anomalous diffusion exponent \(\theta\).

Therefore, by computing \(< \Delta r^2 (t) >\), the value of \(\nu\) can be obtained. An alternative derivation of this result has been proposed in Ref. 27, where the energy integrated Liouvillian propagator is analyzed in the finite \((q, \omega)\) regime and the limits of \(q \rightarrow 0\) and small \(\omega\) are taken.

### III. SHORT RANGE DISORDER POTENTIAL

We introduce next the numerical procedures used to calculate the value of the critical exponent \(\nu\). We do this first in the case of a short-range correlated disorder potential, where we test the effectiveness of these numerical techniques by re-deriving previously known results. We begin by introducing the method used for analyzing
classical localization, where the connection to percolation theory provides a testing ground for our numerics. In subsection 4.1 we describe how the Liouvillian approach is implemented following the method introduced in Ref. [25] to analyze quantum localization. The numerical values thus obtained compare favorably to experimental results and previous numerical calculations.

A. Classical motion

To study the classical motion of the electron’s guiding center along the equipotentials of $V(\mathbf{r})$ we make use of a lattice model, used previously to compute geometrical exponents for contour loops of rough interfaces.

Consider a square lattice $L$ with $N$ sites and periodic boundary conditions. Each site in the lattice has assigned to it a random number that represents the value of the disorder potential $V(\mathbf{r})$ at that point in space. Its dual lattice $L^*$ is the set of points that describe the positions of the electron in this potential landscape. Thus, an electron originally located at a site $\mathbf{r}_0$ of $L^*$ will move along a path that joins points on this lattice. The trajectories are contour loops of the disorder potential. They are generated by first randomly selecting the initial position $\mathbf{r}_0$ from the set of points in $L^*$. The choice of the initial position of the trajectory also fixes the value of the level $V_0$. $V_0$ is computed as the average of the values for $V(\mathbf{r})$ at the four vertexes (sites in $L$) that surround the initial position $\mathbf{r}_0$. Once $V_0$ is determined, all the lattice sites of $L$ can be labeled by + or −, depending on whether they are at a potential higher or lower than $V_0$. The numerical algorithm updates the electron’s position by selecting the bond on the dual lattice that connects the point $\mathbf{r}_0$ with one of its nearest neighbor points, with the additional property that it crosses a ++ or −− bond on the lattice $L$. With this construction, the contour loop is a directed walk along the bonds of the dual lattice $L^*$, that separates potentials lying above (below) $V_0$ on the inside (outside) of the loop (see Fig. 1).

At each step, the square of the displacement vector between the current and original positions on the dual lattice is calculated. The procedure is repeated for different starting points $\mathbf{r}_0$, and different disorder realizations. All the calculated quantities are averaged over all trajectories and over all disorder realizations.

A technical subtlety of this procedure is the existence of saddle-point plaquettes, where there are ++ +− signs cyclically around them. In these cases, two contours (four links) meet at the center and it is necessary to add an additional rule to resolve the connectivity, so as to convert this pattern into two 90° turns that are not quite touching. A physically sensible rule makes use of the average potential $V_{\text{plaq}}$ of the four potentials around the saddle-point plaquette. If $V_{\text{plaq}} < V_0$, the center of the plaquette is at a lower potential than the contour loop and the connectivity is resolved by having the + sites inside the 90° turns. In the opposite case, $V_{\text{plaq}} > V_0$, the + sites are outside of the 90° turns (see Fig. 1).

As in Ref. [14] we find from simulations that the average time for an electron to traverse a certain distance on $L^*$ is proportional to the distance. This observation justifies using the number of steps along $L^*$ to measure the time elapsed. In this way time is rendered dimensionless.

The computations were carried out on two-dimensional square lattices with system sizes $N = 256, 512$ and 1024. The values for the short-range correlated potential were chosen independently from site to site from a uniform distribution over the range $[-0.5, 0.5]$. This choice leads to $V = 0$ for the value of the critical equipotential energy. Fig. 2 shows results for a 1024 x 1024 lattice obtained by averaging over $3 \times 10^4$ trajectories and 1000 different disorder realizations.

As discussed above, the diffusive (slope $\theta = 1$), short-time ($t < t^* \sim 10$), behavior is followed by a crossover to a critical regime where the value of the slope $\theta$ is a measure of the critical exponent $\nu_c$; $\theta = 1 - 1/2\nu_c$. By fitting the critical region to a line on a log-log graph we find

$$\nu_c = 1.25 \pm 0.05$$  \hspace{1cm} (26)

where the error bars reflect the uncertainty associated with choosing the critical region.

This value compares well with the exact result from

\[ \text{FIG. 1: Classical trajectory of the electron’s guiding center, in the presence of a random potential whose values are indicated. } V_0 \text{ is the average potential around the plaquette surrounding the initial point of the trajectory. The resolution of a saddle point is determined by the average potential around the plaquette surrounding the saddle.} \]
percolation theory $\nu_c = 4/3\pi$. The critical regime extends until finite size effects become dominant and $<\Delta r^2>$ saturates, as observed in Fig. 2 for $t > 2 \times 10^4$.

### B. Quantum motion

Following the ideas presented in Sec. 113, we studied numerically the role played by quantum effects on electron dynamics in the lowest Landau level and in the presence of a short-range correlated random potential.

We use the approach proposed in Ref. 113 and use the eigenstates of the Hamiltonian for an electron on a torus geometry as the basis states for the LLL. The corresponding wave-functions written in the Landau gauge are:

$$\psi_\alpha(x,y) = \left[ \sum_{m=-\infty}^{\infty} \exp \left(2\pi i m N + \alpha \right) \left( N m + \alpha \right)^2 \pi \right] e^{-\pi N x^2} \tag{27}$$

where $m$ takes integer values, $N$ is the number of flux quanta through the torus, and the index $\alpha$ goes from 0 to $N - 1$, labeling the $N$ states in the LLL. These wave-functions are periodic functions in the interval $(x,y) \in [0,1) \times [0,1)$, and are centered along narrow strips (of width $\ell_c$) around the lines $x = \alpha/N$; an example is shown in Fig. 113. In Eq. 27, $(x,y)$ are dimensionless variables expressed in units in which the magnetic length is $\ell_c = 1/2\pi N$.

The electron density operator $\rho(k_1,k_2) = \exp(2\pi i (k_1 x + k_2 y))$ projected onto the LLL using this basis, is a matrix of the form:

$$\bar{\rho}(k_1,k_2) = \exp \left(-\frac{k_1^2 + k_2^2}{2N} \pi \right) L(k_1,k_2) \tag{28}$$

where $k_1$, $k_2$ are integers ($(k_1,k_2) \neq (0,0)$), and the matrix $L(k_1,k_2)$ is given in terms of two unitary unimodular $N \times N$ matrices:

$$L(k_1,k_2) = e^{i \frac{\epsilon_1^2 k_1^2 + \epsilon_2^2 k_2^2}{2}} \frac{h^{k_1} h^{k_2}}{\epsilon_1^{k_1} \epsilon_2^{k_2}}$$

$$h = \begin{pmatrix} 0 & 1 & \cdots & 0 \\ 0 & 0 & 1 & \cdots \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & \cdots & 0 \end{pmatrix}$$

$$f = \text{diag}(1,\epsilon,\ldots,\epsilon^{N-1})$$

with $\epsilon = \exp(2\pi i \frac{N}{2h})$; note that $h$ is a cyclic permutation matrix. These matrices satisfy: $hf = f h$ and $h^N = f^N = 1$. The explicit expression for the matrix elements of $L(k_1,k_2)$ is:

$$[L(k_1,k_2)]_{\alpha,\beta} = e^{i \epsilon_1^{k_1} \epsilon_2^{k_2} + k_1 (\alpha - 1) + k_2 (\beta - 1)} \mod N \tag{29}$$

Because the basis of states is restricted to the LLL, the kinetic energy is a constant and the projected Hamiltonian, reduces to:

$$\tilde{H} = \sum_{k_1,k_2} V(-k_1,-k_2) \bar{\rho}(k_1,k_2) \tag{30}$$

$$= \sum_{k_1,k_2} V(-k_1,-k_2) \exp \left(-\frac{k_1^2 + k_2^2}{2N} \pi \right) L(k_1,k_2)$$

where the sum runs over all integer values of $(k_1,k_2)$, and $V(0,0) = 0$ (this choice amounts to fixing the critical energy at zero).

In this basis, the Hamiltonian is a random $N \times N$ matrix that can be diagonalized exactly. Notice that the projection operation introduces the exponential factor in Eq. 27 that effectively reduces the amplitude of the large $(k_1,k_2)$ Fourier components of the potential (it acts as a soft large-momentum cutoff). The presence of this factor seems to indicate that the transition is driven by the small momenta components of the disorder potential. It is important to remark, that even when a numerical calculation procedure fails (due to large but finite precision) to detect the contribution coming from momenta components higher than a maximum value for $(k_1^2 + k_2^2)/2N$ (numerically, the Hamiltonian matrix becomes a banded-matrix), it is incorrect to replace the exponential factor by a hard-cutoff, since the commutation relations of the projected density operator are violated. (In numerical calculations, this translate into...
having results that are extremely sensitive to the value of the hard-cutoff chosen.

The values for the Fourier components of the disorder potential in Eq. (31) are chosen randomly from a flat distribution over the interval $[-0.5, 0.5]$ in units of $\hbar \omega_c$.

We diagonalize the Hamiltonian to obtain all $N$ eigenvalues and eigenfunctions. Figure 3 shows examples of a localized state at the tail of the Landau band, and a delocalized one close to the band center, obtained with a basis of $N = 1000$ states.

A localized wave-packet is constructed with all the eigenstates for a given disorder realization and, as it evolves, its spread along the x-direction is computed as a function of time. The wave-packets are chosen from among the basis states, Eq. (27), which are localized in the x-direction and completely spread out in the y-direction (see Fig. 4a). Thus, the contribution to the total spread from the y-direction is a constant proportional to the system size. Fig. 4 shows a set of ‘snapshots’ for the evolution of the wave-packet initially localized at $x = 0.5$.

The procedure is repeated for different initial positions for the localized wave-packet and different disorder realizations. The spread is averaged over all initial positions and disorder realizations. A typical result for a basis of 1000 states and some 1000 disorder realizations is plotted in Fig. 5.

As in the classical case, three regimes can be identified. For long enough times ($t > 10$ in Fig. 5), the spread of the wave-packet reaches a constant value indicating the influence of the finite system size. The critical region corresponds to intermediate times ($0.4 < t < 10$), and the value of $\nu_q$ (“q” for quantum) can be related to the slope of the line, which is the anomalous diffusion exponent $\theta$ (see Eq. (25)). As seen in the inset to Fig. 5, the slope in the critical region shows a strong dependence on the system size. To take into account these finite size effects, we determined the slope for systems sizes ranging from $N = 200$ to $N = 1500$ and compute the value for an infinite sized system by linear extrapolation to obtain $\nu_q = 2.33 \pm 0.09$.

Our result compares favorably to the values measured in experiments ($\nu = 2.3 \pm 0.1$) and previous numerical simulations ($\nu = 2.35 \pm 0.05$). This provides an important check on the numerical method.

Our data shows that at very short times the slope $\theta \approx 2$ which implies ballistic spreading of the wave-packet. In the Appendix we present a calculation based on perturbation theory that shows that this is a result of averaging the evolution equation over random disorder, at short enough times.

IV. POWER-LAW CORRELATED DISORDER POTENTIAL

In this section we address the central issue raised by the present work: how a change in the properties of the probability distribution for the disorder potential affect the nature of localization in the lowest Landau level. The numerical procedure outlined in previous sections allows us to investigate this point in a straightforward manner for both the classical and the quantum regime. Basically, it amounts to an appropriate modification of the probability distribution for the Fourier components for the random potential in Eq. (31). Since we are interested in the effect of power-law correlations on localization properties of the Hamiltonian in Eq. (31), the Fourier components are chosen independently with a Gaussian distribution with zero mean, and variance

$$\langle |V(k)|^2 \rangle \propto 1/|k|^{2-\alpha}.$$  (31)

Inverse Fourier transforming to real-space leads to power-law correlations

$$V(r)V(0) \sim 1/|r|^\alpha.$$  (32)

The constant in Eq. (31) is fixed so that the variance of $V(r)$ is normalized to one. Long-range correlations strongly modify the real-space configuration of the
FIG. 4: Evolution of a wave-packet made of all eigenstates that is initially localized at $x = 0.5$. The squared amplitude of the wave-packet is plotted as a function of the real space coordinates $(x, y)$ at four different times.

equipotential lines as can be seen in Fig. 6 where a comparison between a short-range and a power-law correlated potential with $\alpha = 0.5$ is given.

A. Classical motion

In the classical limit of the IQH transition, the effect of power-law correlations in the disorder potential can be described in terms of a purely geometric effect: they change the fractal geometry of the equipotential contours modifying the electron’s path, and correspondingly, the anomalous diffusion law for its mean squared displacement.

To study numerically this regime, we repeated the procedure described in Sec. III A and computed $\langle \Delta x^2(t) \rangle$ for values of $\alpha$ ranging from 0.33 to 1.8. Fig. 7 shows the curves obtained for a system of 512 x 512 lattice sites. As in the case of short-range correlations, three regimes can be identified with the onset of each of them depending on the value of $\alpha$. From the figure, a qualitative change in the spread of the electrons position in time is observed. Namely, in the critical regime (typically for $30 < t < 1100$), the value of the slope becomes dependent on $\alpha$ when $\alpha \leq 1.5$. As the value of $\alpha$ decreases (correlations increase) below a critical value of $\alpha_c \approx 1.5$ (‘c’ is for ‘classical’), the slope $\theta$ in the critical region increases and $\nu$ becomes an increasing function of $\alpha$ tending to infinity as $\alpha$ approaches zero.

B. Quantum motion

In contrast to the classical regime, the effect of power-law correlations in the disorder potential on the properties of quantum localization, does not have a simple geometrical interpretation. In particular, we find that changing the fractal properties of the equipotentials does not always lead to a change in the quantum critical exponents.

The numerical procedure introduced in Sec. III B is easily extended to the present case allowing us to study
the problem in detail. The Fourier components of the random potential are taken from the same distribution as in the classical case and the corresponding quantum Hamiltonian (Eq. (31)) is diagonalized. Then, $\langle \Delta x^2 \rangle$ is computed as a function of time for values of $\alpha$ ranging from 0.1 to 1.9. A typical set of results obtained with a basis of 1000 states is shown in Fig. 8 together with the curve obtained for a short-range correlated potential. As in the short-range case, the exponent $\theta$ was calculated for different systems sizes ranging from $N = 300$ to $N = 1000$.

Like in the classical case, a qualitative difference in the slopes of the critical regime develops as $\alpha$ changes. A careful comparison among the different curves shows that the value of the slope in the critical region starts to increase below a critical value of $\alpha^* \approx 0.85$. A detailed quantitative analysis of these results together with a comparison to the classical case is the subject of the following section.

V. EXTENDED HARRIS CRITERION

The effect of a random disorder potential on the properties of continuous phase transitions in classical systems is summarized by the Harris criterion\(^\text{15}\). Basically, the criterion states that critical exponents of the disordered and the corresponding clean system remain equal as long as the value for the correlation length exponent $\nu$ satisfies: $d\nu - 2 \geq 0$, where $d$ is the dimensionality of the classical system under consideration. The criterion is derived by requiring that the fluctuations of the thermodynamic quantity which couples to the disorder, within a volume set by the correlation length $\xi$, do not grow faster than its average value, as the transition is approached and $\xi \to \infty$. It was proved rigorously and generalized to a wider class of systems if an appropriate definition for the correlation length is adopted\(^\text{15}\). An extension of the criterion to power-law correlated disorder was proposed by Weinrib and Halperin\(^\text{16}\).

In the case of two-dimensional percolation with power-law correlations in the occupation probabilities, with the power-law exponent $\alpha$, the extended Harris criterion states:

$$\alpha > \alpha^*_c = \frac{3}{2} \quad \nu_c = \frac{4}{3}$$

$$\alpha < \alpha^*_c = \frac{3}{2} \quad \nu_c = \frac{2}{\alpha}.$$  \(\text{(33)}\)

As a numerical check on Eq. (33), we computed the values of the anomalous diffusion exponent $\theta$ for classical electron motion and plotted them as a function of $\alpha$ in Fig. 9. The values of $\theta$ were obtained from fitting the data
in Fig. 7 in the critical region, to a line using a least-squares method; \( \theta \) is the slope of the line. We see that the data is well described by the theoretical prediction: above \( \alpha^*_c = 3/2 \) the anomalous diffusion constant \( \theta = 1 - 1/2\nu_c = 5/8 \) is constant, while below this value it varies as \( \theta = 1 - \alpha/4 \). Similar results were obtained previously by Prakash et al.\textsuperscript{32}.

Analogous results hold true for the quantum case. In Fig. 8, we plot the anomalous diffusion exponent \( \theta \), which describes the spreading of an initially localized wave-packet in the lowest Landau level, as a function of \( \alpha \). The exponent \( \theta \) was computed using the data in Fig. 8 following the same procedure as in the classical case. The values plotted are the extrapolation corresponding to an infinite system size. We see that the numerical results presented in Fig. 8 are in good agreement with the extended Harris criterion which now reads:

\[
\begin{align*}
\alpha &> \alpha^*_q \approx 0.85 \quad \nu_q \approx 2.33 \\
\alpha &< \alpha^*_q \approx 0.85 \quad \nu_q = \frac{2}{\alpha}.
\end{align*}
\]

(34)

Support for the validity of the extended Harris criterion for quantum critical points was also provided by studies of random quantum magnets\textsuperscript{33}.

In the case of quantum percolation (i.e., localization in the lowest Landau level) the extended Harris criterion can be argued for in close analogy to the classical case.\textsuperscript{16} Namely, consider the average size of the fluctuations of the electron’s energy in an area set by the localization length \( \xi \). Like the electron’s energy, it is also determined by the random disorder potential, and can be approximated as:

\[
E^2 \approx \frac{1}{\xi} \int_{\xi^2} d^2x V(x)^2 
\sim \frac{1}{\xi} \int_{\xi^2} d^2x |x|^{-\alpha}
\]

(35)

where in deriving the second equation we have made use of \( < V(x)V(x') > \sim 1/|x - x'|^{\alpha} \).

For the quantum critical point associated with localization in the lowest Landau level to be stable to the introduction of power-law correlations in the random potential, the fluctuations in the electron’s energy should be
small when compared to its energy \( E \). Using Eq. \( \ref{eq:33} \), and the scaling relation \( E \sim \xi^{-1/\nu} \) we arrive at the estimates

\[
\frac{E^2}{\xi^2} \sim \begin{cases} 
E^{2\nu-2} & : \alpha > 2 \\
E^{2\nu-2} \ln(E)^{-\nu} & : \alpha = 2 \\
E^{\alpha-2} & : \alpha < 2 
\end{cases} . \tag{36}
\]

The quantum percolation critical point is expected to be unaffected by the introduction of power-law correlations if \( \frac{E^2}{\xi^2} \rightarrow 0 \) when \( E \rightarrow 0 \), or, equivalently, when \( \xi \rightarrow \infty \). Since \( \nu > 1 \) this is always the case when \( \alpha \geq 2 \).

However for \( \alpha < 2 \) there are two regimes to consider. When \( 2 > \alpha > 2/\nu, \frac{E^2}{\xi^2} \rightarrow 0 \) and the localization critical point due to short-ranged potential disorder is again stable to introduction of power-law correlations in the random potential. In contrast, for values of \( \alpha < 2/\nu \) a power-law correlated potential produces large fluctuations in the energy thus destabilizing the critical point.

The usual expectation is that this relevant perturbation leads to a new quantum critical point characterized by a new value of \( \nu \). This is confirmed by our numerical results.

An important consequence of the present result regards the validity of the expression put forward in Ref. \( \ref{ref:34} \) that relates the values of \( \nu_q \) and \( \nu_c \) as follows:

\[
\nu_q = \nu_c + 1 \tag{37}
\]

According to the analysis presented above, a quantum system with a long-range correlated potential has the same critical exponent as one with short-range correlations as long as \( \alpha \geq 0.85 \). However, a classical system with potential correlations with a value for \( \alpha \) in the region \( 0.85 < \alpha < 1.5 \), has a continuously varying critical exponent \( \nu \) according to Eq. \( \ref{eq:33} \). For instance, a value of \( \alpha = 1 \) gives \( \nu_q = 2.33 \) while \( \nu_c = 2.0 \). This analysis suggests that the relation given by Eq. \( \ref{eq:34} \) (whatever the argument used to support it) is inconsistent with the Harris criterion.

VI. COMPETING DISORDERS

In this section we undertake a numerical study of the effect of competing disorders on localization in the LLL. We investigate first the classical regime, which is in the universality class of correlated percolation. Analytical calculations have shown that in these systems the classical critical point generated by a long-range correlated potential is stable against perturbations produced by a short-range correlated potential. As shown below, our numerical results in this regime, provide support for this picture.

In the quantum case we investigate the effect of competing power-law correlated and short-range correlated disorders on localization. Numerical studies of this particular case are relevant for experiments attempting to measure properties of the correlated quantum percolation critical point. Namely, since short-range correlated potentials are always present in experimental setups, it is important to understand quantitatively how their presence affects the values of the new localization length exponents described in the previous sections.

To proceed with the appropriate numerical model we first establish the following conventions. The total disorder potential is defined as a weighted sum of two potentials: one with short-range correlations \( V_s(\mathbf{r}) \) and one with long-range correlations \( V_l(\mathbf{r}) \). The units chosen are such that the mean values of short- and long-range correlated potentials are set equal to zero while their variances are normalized to one. In this way, the maximum amplitudes of both potentials are comparable. In order to vary the relative strength of each potential we introduce a parameter \( \kappa \) with values in the range \( 0 \leq \kappa \leq 1 \) such that the total potential is:

\[
V_{\text{eff}}(\mathbf{r}) = \kappa V_s(\mathbf{r}) + (1 - \kappa) V_l(\mathbf{r}) . \tag{38}
\]

Notice that when \( \kappa = 0 \) the total potential has power-law correlations only, while the short-ranged part is increasingly dominant as the value of \( \kappa \) increases toward 1. This definition ensures that the variance of the total potential \( V_{\text{eff}}(\mathbf{r}) \) remains fixed as \( \kappa \) changes and \( \langle V_{\text{eff}}^2(\mathbf{r}) \rangle = 1 \).

The numerics were performed with short-range correlated potentials constructed from random Fourier components \( V(\mathbf{k}) \) sampled from a uniform distribution, and from a Gaussian distribution with variance \( \sim |\mathbf{k}|^{\alpha-2} \) with \( \alpha > \alpha^* \). In real space this leads to delta-correlations and power-law correlations with exponent \( \alpha \), respectively. Long-range correlated potentials were generated with power-law correlations with exponent \( \beta < \alpha^* \), for which the extended Harris criterion predicts a new localization
TABLE I: Statistical properties of the short-range and long-range correlated potentials used in section VI

| Potential | Exponent | Correlation |
|-----------|----------|-------------|
|\(V_{\text{eff}}(r)\) | \(\kappa V_{\text{r}}(r) + (1 - \kappa) V_{\text{f}}(r)\) | - |
|\(\langle V_{\text{r}}(r) \rangle = \langle V_{\text{f}}(r) \rangle\) | 0 | - |
|\(\langle V_{\text{r}}^2(r) \rangle = \langle V_{\text{f}}^2(r) \rangle\) | 1 | - |
|\(\langle V_{\text{r}}(r) V_{\text{f}}(r') \rangle\) | \(|r - r'|^{-\alpha}, \delta(r - r')\) | - |
|\(\langle V_{\text{r}}(r) V_{\text{r}}(r') \rangle\) | \(|r - r'|^{-\beta}\) | - |

The properties of the total potential and its components is summarized in Table I:

A note on the evaluation of errors: as it will be shown in the following sections, the effect of tuning \(\kappa \neq 0\) depends on system size for both classical and quantum regimes. Hence, it was not possible to carry out the finite-size study similar to the one done previously, where there is only one type of disorder present. As a consequence, the errors have been estimated from the largest systematic error involved in the procedure, which appears in the determination of the slope of the critical region.

A. Classical Regime

Computations were carried out for system sizes \(N = 256, 512\) and \(N = 1024\). The values of the anomalous diffusion exponent \(\theta\) were extracted from the critical region of the spread of the classical position of the electron, as in section IV A. Values of \(\theta\) were obtained for a range of values of the parameter \(\kappa\). Fig. 11 shows result that correspond to a combination of a power-law correlated potential with exponent \(\beta = 0.5\) (for the long-range part) and \(\alpha = 1.8\) (for the short-range piece).

In contrast to the classical regime, up to date, there is no experimental or theoretical work to our knowledge that attempted to investigate the influence of mixed long-range and short-range correlated disorder potentials on the integer quantum Hall transitions. The numerical strategy used in section IV B provides us with a framework to study this situation and allows us to examine the stability of newly found quantum critical points.

Computations for quantum systems were carried out with a basis of \(N = 500, 700\) and \(N = 1000\) states. The values of the slope \(\theta\) were extracted from the critical region and plotted as a function of the parameter \(\kappa\), as in the classical regime. The results shown in Fig. 12 were obtained with power-law correlated potentials \(V_{\text{r}}\) and \(V_{\text{f}}\) with exponents \(\alpha = 1.8\) and \(\beta = 0.5\), respectively.

As the figure shows, data for the quantum regime is noisier than its classical counterpart. Finite size effects are also more prominent as can clearly be observed in the variation of the values of the slope \(\theta\). However, the trend observed is in agreement with the expected behavior in the thermodynamic limit. It suggests that the new quantum correlated critical points are indeed stable against the perturbation introduced by a short-range correlated potential. This opens up the prospect of measuring the new localization length exponents \(\nu_{q}\) in experiments in which random disorder with power-law correlations is introduced. The idea would be to engineer a random potential with desired properties which would then compete with the short-range disorder due to the presence of impurities in the semiconductor heterostructure. An example of such a system was described in Ref. 8, where a thin magnetic film was placed in close proximity to the two-dimensional electron gas resulting in a random length exponent \(\nu = 2/\beta\). The properties of the total potential and its components is summarized in Table I:

The figure shows that, as the system size increases the value of \(\theta\) (and hence of \(\nu\)) remains closer to the pure long-range value up to fairly large values of \(\kappa\) (roughly 55% – 60%). The increasing sharpness of the crossover with increasing system sizes suggests a very sharp crossover in the thermodynamic limit. In the language of renormalization group, this is an indication of the stability of the long-range critical point when perturbed with a short-range correlated potential. Notice, as it was pointed out above, that this crossover is strongly dependent on the system size, rendering useless the finite-size scaling analysis used previously. An interesting effect is observed in the raw data that points to the way the crossovers occur in finite size systems. Between the initial crossover from diffusive to sub-diffusive motion and the final crossover from sub-diffusive motion to saturation, there are two clearly distinguishable regimes. At the earlier times, the slope is determined by the short-range correlated potential. Only at latest times (and before saturation effects dominate), a new slope appears that corresponds to the value of \(\theta\) determined by the exponent of the power-law (long-range) correlated potential.

B. Quantum Regime

FIG. 11: Classical regime: slope \(\theta\) as a function of parameter \(\kappa\). \(\kappa = 0(1)\) indicates a pure long-range (short-range) correlated potential.

As the figure shows, data for the quantum regime is noisier than its classical counterpart. Finite size effects are also more prominent as can clearly be observed in the variation of the values of the slope \(\theta\). However, the trend observed is in agreement with the expected behavior in the thermodynamic limit. It suggests that the new quantum correlated critical points are indeed stable against the perturbation introduced by a short-range correlated potential. This opens up the prospect of measuring the new localization length exponents \(\nu_{q}\) in experiments in which random disorder with power-law correlations is introduced. The idea would be to engineer a random potential with desired properties which would then compete with the short-range disorder due to the presence of impurities in the semiconductor heterostructure. An example of such a system was described in Ref. 8, where a thin magnetic film was placed in close proximity to the two-dimensional electron gas resulting in a random
magnetic field. By controlling the height fluctuations of the film one can in principle engineer a random potential with desired correlations.

VII. CONCLUSIONS

We have analyzed the effect of spatial correlations of the disorder potential on the localization-delocalization transition in the integer quantum Hall system. The main purpose of the analysis was to understand separately the role played by quantum effects and disorder on the critical properties of the transition by comparing classical and quantum localization.

The analysis of electron localization in the classical case reveals that the localization length exponent is completely determined by the statistical properties of the level lines of the random potential. Using the tools of percolation theory, we were able to implement well-established numerical methods to perform a detailed check of the validity of the Harris criterion. We found numerical support for the extended version of the criterion, confirming previous theoretical arguments.

The quantum regime was analyzed by studying the real time density-density propagator as proposed in Ref.28. This method, originally introduced as an alternative way to calculate the critical exponent $\nu$ for a short-range correlated potential, proved to be an excellent testing ground to analyze the role of disorder. We obtained (following a rather simplistic finite size analysis) a value for $\nu = 2.33 \pm 0.09$ remarkably close to experimentally measured values and numerically calculated ones. We also found that when the decay of power-law correlations of the random potential is slow enough this can destabilize the quantum critical point and lead to new critical behavior, as predicted by the extended Harris criterion.

Comparison between classical and quantum regimes with long-range correlated disorder potentials, indicate that the effect of disorder correlations are qualitatively similar for quantum and classical systems. The main difference between these two cases seems to be the critical value of $\alpha$ (the exponent determining the long-range correlations) below which the value of $\nu$ is changed. The value of $\alpha^* \simeq 0.85$ is smaller compared to its classical counterpart $\alpha^*_c = 1.5$. This suggests that quantum fluctuations can be thought of as effectively smearing out the correlations in the random potential thus shifting $\alpha^*$.

An immediate consequence of these results is that in the quantum case, there is no direct connection between the statistical properties of equipotential lines and the localization length exponent. Specifically, we were able to show that the fractal geometry of the equipotential lines can be continuously varied while the quantum localization length exponent does not not change.

The detailed numerical study of the variation of the critical exponent $\nu$ with the power-law exponent $\alpha$, led us to propose a precise statement for the quantum version of the extended Harris criterion. These numerical results are supported by a scaling argument, in close analogy with the classical case.

In order to address the experimentally relevant situation of samples with disorder potentials of different origins and likely, different correlations, we analyzed the effect of competing correlations in disorder potentials on the IQHT. In the semi-classical limit, our numerical results give support to previous theoretical arguments for the stability of the classical correlated-percolation critical points. In the quantum regime we observed that, while the value of the critical exponent $\nu$ varies as the short-range correlated potential is introduced, the trend is similar to the one observed in the classical regime. As a consequence, our results show no qualitative difference between classical and quantum regimes regarding the stability of these critical points. More importantly, they point to the possibility of seeing effects of the correlated quantum percolation critical points in experiments on two-dimensional electron gases in semiconductor heterostructures where short-range disorder due to impurities is unavoidable.

It is a pleasure to acknowledge useful conversations with B. Halperin, J. Sinova, V. Gurarie, S. Boldyrev, J. Moore, H. Castillo, S. Simon and G. Murthy. JK is supported by the NSF under grant number DMR-9984471, and is a Cottrell Scholar of Research Corporation.

APPENDIX

In this appendix we present a calculation based on perturbation theory that shows that at short times the wave-packet has a ballistic spread, which is what was observed numerically. If $|\psi(t)|$ is the wave-function of the wave-packet at time $t$, the spread is given by:
\langle \psi(t) | \Delta x^2 | \psi(t) \rangle = \langle \psi(t) | x^2 | \psi(t) \rangle - \langle \psi(t) | x | \psi(t) \rangle^2 \quad (A.1)

Here we analyze the first term in detail, while the second one can be dealt with in a similar way. In the Heisenberg representation:

\langle \psi(t) | x^2 | \psi(t) \rangle = \langle \psi(0) | x^2(t) | \psi(0) \rangle \quad (A.2)

where

\begin{equation}
x^2(t) = e^{iHt} x^2(0) e^{-iHt}. \quad (A.3)
\end{equation}

Using the well known operator identity:

\begin{align}
\langle \psi(t) | x^2 | \psi(t) \rangle &= \langle \psi(0) | x^2(0) | \psi(0) \rangle +\nonumber \\
&+ it \langle \psi(0) | [H, x^2(0)] | \psi(0) \rangle + \frac{(it)^2}{2!} \langle \psi(0) | [H, [H, x^2(0)]] | \psi(0) \rangle + \mathcal{O}(t^3). \quad (A.4)
\end{align}

The probability distribution of energies is determined by the probability distribution of the disorder potential, which is chosen to be symmetric around the value \( V = 0 \). Since the wave-packet contains all the eigenstates, the averaging over disorder (average over energies) eliminates the linear term in the expansion above. Thus, the first non-vanishing contribution at short times is given by the quadratic term which corresponds to a ballistic spread.
