Is CABG the preferred method of revascularization in multivessel coronary artery disease?

Hannan EL, Racz MJ, Walford G, Jones RH, Ryan TJ, Bennet E, et al. Long-term outcomes of coronary-artery bypass grafting versus stent implantation. N Engl J Med 2005;352(21):2174-83.

**Background:** Clinicians still debate the merits of percutaneous coronary intervention (PCI) relative to coronary artery bypass grafting (CABG) for patients with multivessel coronary artery disease. To date, only 4 randomized clinical trials have compared the outcomes of PCI and stent implantation with those of CABG. Such studies have been too highly selective, small and underpowered to demonstrate a consistent and compelling mortality advantage of one modality over the other.

**Design:** This retrospective study compared outcomes for 22,102 patients undergoing PCI and stenting with 37,212 patients undergoing CABG between Jan. 1, 1997, and Dec. 30, 2000. Primary outcomes included mortality and subsequent revascularization within 3 years. Patients were further categorized into 5 anatomic subgroups depending on their number of diseased vessels and presence or absence of disease involving the proximal left anterior descending coronary artery (LAD). Mortality analyses were adjusted for disease severity through use of a multivariate Cox proportional hazard model.

**Results:** Compared with patients who underwent PCI, those who underwent CABG were older and at baseline were more likely to have disease affecting 3 vessels, a lower ejection fraction and a high prevalence of comorbidities including cerebrovascular and peripheral vascular disease, diabetes and renal failure. Subsequent rates of revascularization were significantly lower among patients who received CABG rather than stenting. Although the in-hospital mortality rate was significantly higher in the CABG group than in the stenting group (1.75% v. 0.68%, p < 0.001), the converse was true for long-term mortality. Specifically, the adjusted 3-year mortality rates were lower among CABG patients, regardless of their anatomic distribution of disease, existence of diabetes or impairment of left ventricular function. The survival benefits associated with CABG were more pronounced and consistent among patients with 3-vessel disease and involvement of the proximal LAD (adjusted hazard ratio [HR] 0.64, 95% confidence interval [CI] 0.56–0.74) than among those with 2-vessel disease and nonproximal LAD involvement (adjusted HR 0.76, 95% CI 0.60–0.96; Table 1).

**Commentary:** The advantages of this study included its large sample, clinical detail and ability to adjust for differences in clinical and anatomic characteristics. Moreover, the advantage associated with CABG persisted despite the fact that these patients were modestly older and had more comorbidities at baseline than those receiving PCI. The outcome benefits observed to be associated with CABG rather than PCI were also biologically plausible and consistent with the findings of at least 1 meta-analysis, which combined stented and nonstented patients. The study has 2 important limitations: First, its observational design would not have adequately accounted for unmeasured confounding factors. Second, these findings may not be generalizable to the Canadian health care system, where delays before such interventions may occur. Moreover, the technology for both treatments is rapidly changing, most notably with the introduction of drug-eluting stents.

**Practice implications:** These results suggest that long-term outcomes in patients with multivessel disease may be superior with CABG than with stent implantation. Nonetheless, physicians must still consider multiple factors when choosing a revascularization modality. First, the long-term survival benefit associated with CABG must be weighed against the higher incremental short-term (in-hospital) risks of complications and death related to the procedure. Accordingly, such decision-making must take into account the patient’s comorbidities and preferences.

**Table 1: Hazard ratios* for death after CABG compared with those after stenting**

| Disease location       | 2-vessel disease, n | Hazard ratio (95% CI) | 3-vessel disease, n | Hazard ratio (95% CI) |
|------------------------|---------------------|-----------------------|---------------------|-----------------------|
|                        | Stent               | CABG                  | Stent               | CABG                  |
| No LAD disease         | 5 847               | 1 309                 | 0.75 (0.58–0.98)    | –                     | –                     |
| Proximal LAD           | 6 033               | 8 410                 | 0.75 (0.66–0.86)    | 2 165                 | 20 857                | 0.64 (0.56–0.74)      |
| Nonproximal LAD        | 5 891               | 1 690                 | 0.76 (0.60–0.96)    | 2 166                 | 4 946                 | 0.74 (0.62–0.90)      |

*Adjusted for age, sex, ejection fraction, and presence or absence of diabetes, congestive heart failure, chronic obstructive pulmonary disease, carotid artery disease, aortic valve disease, shock, renal failure, femoral or popliteal disease, and stroke.

account patient preferences, competing risks and natural life-expectancy. Second, inter-regional and interhospital variations in procedural availability may circumvent or mitigate adverse consequences that may be associated with service delays. In short, decisions about which revascularization procedure to use still require sound clinical judgement in the context of evidence-based medicine.
