Summary

The anterior cerebral artery is a common location of intracranial aneurysms. The standard coil embolization technique is limited by its inability to occlude wide-neck aneurysms. Stent deployment across the aneurysm neck supports the coil mass inside the aneurysmal sac, and furthermore, has an effect on local hemodynamic and biologic changes. In this article, various management strategies and techniques as well as angiographic outcomes and complications related to stent-assisted endovascular treatment of anterior communicating artery aneurysms are presented. This treatment method is safe and associated with low morbidity and mortality rates.

MeSH Keywords: Embolization, Therapeutic • Endovascular Procedures • Intracranial Aneurysm

Background

Intracranial aneurysms are found in approximately 2% of adults [1]. Most of the unruptured aneurysms are asymptomatic and discovered incidentally but rupture of aneurysm results in a potentially life-threatening subarachnoid hemorrhage (SAH). In most series the anterior communicating artery (AcomA) is the most common location for intracranial aneurysms and ruptured aneurysms of this artery are the cause of 40% of aneurysmal subarachnoid hemorrhages in adults [2]. Either unruptured or ruptured brain aneurysms may be treated surgically or via endovascular approach. The main treatment goal of both methods is to exclude the aneurysm from circulation in order to prevent hemorrhage or rehemorrhage. Although surgical clipping of AcomA aneurysms is acknowledged to be a safe and effective procedure, it may be technically challenging because of deep midline aneurysm location, presence of small vessels and perforators, unfavourable fundus projection, frequent anatomy variations and the higher risk of postoperative cognitive impairment [2–6]. It is reported that AcomA aneurysms demonstrate the highest incidence of postoperative morbidity among all anterior circulation aneurysms [7].

Endovascular techniques in treatment of AcomA aneurysms

Endovascular embolization is a less traumatic treatment option of brain aneurysms and with its high feasibility and effectiveness in AcomA aneurysms it is becoming the leading method [2,4,8]. In comparison with the other intracranial aneurysms embolization of AcomA aneurysms may be difficult due to the high frequency of small or complex aneurysms and common vascular variants in this location [5]. However, endovascular approach remains the first choice technique in cerebral aneurysms treatment in many neurosurgical centres. The primary technique of endovascular treatment of the cerebral aneurysms is coil embolization (coiling). In this method detachable coils are deployed within the aneurysm lumen. Unfortunately, the application of coiling is limited in case of aneurysms with unfavourable anatomy. Aneurysms with a “wide neck” are difficult to treat because of the risk of coil protrusion into the parent vessel or the high probability of incomplete occlusion [9,10]. Wide-necked aneurysms are defined as those with maximum neck width of 4.0 mm or those with aneurysm dome-to-neck ratio (maximum dome width/maximum neck width) of <2.0 or <1.5 [10–14]. Endovascular treatment of wide-necked AcomA aneurysms requires application of
adjunctive techniques of which the two most widespread are balloon remodelling technique (BRT) and stent-assisted coiling technique (SACT), methods primarily applied for endovascular treatment of sidewall aneurysms. In BRT a balloon is temporarily deployed and inflated across the aneurysm neck. Then coils are placed into the aneurysm sac and the balloon is removed [9]. Compared with SACT the balloon remodelling technique is associated with lower rate of aneurysm obliteration, lower rate of progression of occlusion at follow-up, higher rate or retreatment and similar procedural complication rate [15]. Moreover, in case of extremely wide-necked aneurysms BRT is inadequate [5].

First described by Higashida in 1997 SACT has widened the range of options for the treatment of wide-necked aneurysms, including AcomA aneurysms [5,6,16–19]. Because of a small length of the AcomA and acute angles of adjacent vessels, application of adjunctive techniques in endovascular treatment of AcomA aneurysms in relation to the other cerebral aneurysms is technically challenging [5,20]. A self-expandable stent serves as a scaffold which prevents the coil protrusion into the parent artery and results in denser coil packing [21]. Moreover, a stent may be deployed in case of earlier coil protrusion into the parent vessel as a prevention of a thromboembolic event [5,17,18,22]. In addition to their mechanical function, stents are reported to have hemodynamic effects as they redirect blood flow from the sac of the aneurysm toward the distal parent artery. That contributes to thrombosis of the aneurysmal sac and decreases the likelihood of recanalization [7,23]. Biological effects of intracranial stents are associated with stent-induced neointimal overgrowth [24].

There are various intervention techniques depending on the time of stent deployment in relation to coiling (Figure 1) [5,6,18,25]. In case of the treatment of wide-necked AcomA aneurysms, stents are commonly placed prior to coiling [5,6,18]. In the “jailing” technique the embolization microcatheter is navigated into the aneurysm before deployment of the stent [6,26]. The microcatheter placed between the vessel wall and the stent is stabilized during coiling. Another option is to place the microcatheter into the aneurysm lumen through the stent struts after deploying of the stent (trans-cell technique) [9]. However, crossing a deployed stent with a microcatheter may be technically challenging [26]. Raslan et al. reported this method as difficult and used the “jailing” technique as the first-choice method in the treatment of AcomA aneurysms, while Huang et al. deployed stents first [5,6]. According to this author the application of the “jailing” technique in endovascular embolization of AcomA aneurysms is limited due to the small diameter of ACA and vasospasm resulting from SAH [5]. Raslan et al. presented three possible stent placement configurations across the AcomA aneurysms (Figure 2). Stent may be deployed from ipsilateral A1 to contralateral A2 (most commonly), from ipsilateral A1 to ipsilateral A2 (less commonly) and from ipsilateral A1 to contralateral A1 segment (least common configuration) [6]. Huang in his study deployed stents in the ipsilateral A2 segments more commonly than in the contralateral A2 segments [5]. The strategy of stent placement depends on aneurysm neck location and symmetry of the anterior cerebral arteries [5]. Stent-assisted coiling of wide-necked and complex AcomA aneurysms may be challenging due to their anatomic and geometric features [20,27,28]. In such cases implantation of 2 stents (i.e. dual stent placement) in X- or Y-configuration or the “waffle cone” technique may be used (Figure 3) [20,27,28]. The X-configured dual stent placement is a feasible method for the treatment of wide-necked AcomA aneurysms involving both A1-A2 junctions where the AcomA is partly incorporated within the sac and both A2s protrude from the aneurysm [7]. In such technically challenging aneurysms (also from the surgical point of view) the first stent is deployed from the contralateral A2 to the ipsilateral A1 segment, crossing through the AcomA and the second stent is crossed from the other side [7,9]. The side with the smaller angle between the A1 – AcomA complex and the contralateral A2 segment is stented first [9]. The stents may be placed using two different methods. In the kissing technique stents are deployed in a parallel fashion while in the crossing technique a second stent is advanced through the first stent interstices [9]. In comparison to ipsilateral placement of stents with an “opposite L” configuration (i.e. deploying stents from the ipsilateral A2 to the A1 segment) the X-stent technique may be used in case of small angles between the A1-A2 segments [7]. Moreover, the latter technique preserves the patency of AcomA and alters flow direction at the neck of the aneurysm which may have an impact on long-term durability [7]. However, this technique is to be reserved for patients having good-sized A1s, bilaterally [7]. On the other hand, Y-configured dual stent placement is an option for patients with hypoplasia/aplasia of A1 on one side and complex AcomA aneurysms when the aneurysm neck involves the ipsilateral A2 and AcomA [7,20]. In this method stents are deployed through the large-sized A1 in the

![Figure 1. The illustration presents two different stent deployment techniques with respect to microcatheter insertion. The “jailing” technique depicted on the left side and the trans-cell technique on the right side. The final effect is the same.](image-url)
bilateral A2 segments [7,20]. In the “waffle cone” technique the distal end of a stent is placed into the aneurysm lumen and the proximal end of a stent is left in the afferent vessel (intra/extra-aneurysmal placement) [27,28]. This method allows for preservation of the parent artery patency. Coiling is done through the cone-shaped distal end of the stent [27]. The waffle cone technique may be a good alternative to dual stent placement in case of aneurysms incorporating bilateral A2 segments or involving the AcomA or if there is a difficulty in selecting a distal major vessel due to acute angles between the parent and distal arteries [5,27]. However, this technique carries a potential risk of aneurysm perforation, especially in freshly ruptured or smaller (<4 mm) aneurysms and the rate of recanalization due to flow direction in the aneurysm may be higher [5,27].

There are two types of stent designs depending on the size of cell areas and the type of connections between stent struts: open-cell design (Neuroform stents) and closed-stent design (Enterprise, LEO and Solitaire stents). All the aforementioned devices are self-expandable and made of nitinol (nickel titanium) [26]. The first stent assisting the treatment of a brain aneurysm with coils was the Neuroform stent, approved in 2002 [26]. The Neuroform stent has a longer record of use and is more established in the treatment of AcomA aneurysms than the Enterprise stent, its principal alternative. The latter is more flexible, easier to deploy and navigate. Furthermore, the advantage of the closed-stent design is higher effectiveness in keeping coils within an aneurysm [29,30]. In comparative analyses both Neuroform and Enterprise stents were reported to be safe and effective with comparable morbidity rates [31].

**Angiographic outcome and recanalization**

A meta-analysis conducted in 2013 concerning outcomes of embolization of AcomA aneurysms showed that non-stent and stent-assisted coiling of AcomA aneurysms is associated with a high rate of complete angiographic occlusion [2]. In this study the rate of immediate and long-term complete and near-complete angiographic occlusion was 88% and 85%, respectively [2]. In case of complete occlusion there is absence of contrast medium filling within the coil mass. Near-complete occlusion is defined as small residual neck filling without any filling of the sac and in contrast to the residual aneurysm it requires no retreatment [2,6]. Angiographic results of three stent-assisted AcomA aneurysm embolization series showed that the complete and near-complete occlusion rate was 66–95% initially and 88–95% at follow-up [5,6,18]. Detailed data are presented in Table 1. Stent-assisted coil embolization of intracranial aneurysms is associated with a lower rate of immediate complete aneurysm occlusion compared with non-stent procedures [32]. One of the reasons is that coiling after stent deployment may be technically more difficult due to the limited manoeuvrability of the coiling microcatheter resulting in looser aneurysm packing [32]. On the other hand, stented aneurysms demonstrate a higher rate of delayed sac thrombosis at follow-up than non-stented ones [32]. Johnson et al. observed angiographic improvement (i.e. delayed aneurysm occlusion) at 6-month follow-up in 17 (63%) of 27 patients with initially incomplete occlusion after stent-assisted AcomA aneurysm coiling [18]. The reduction of aneurysm sac opacification is likely to result from delayed intra-aneurysmal thrombosis [20]. There are case reports demonstrating delayed aneurysm sac thrombosis when stent is placed across the aneurysm neck without coiling but these reports do not include AcomA aneurysms [33–36]. It is suggested that expected delayed intra-aneurysmal thrombosis should be taken into consideration in case of incomplete immediate stent-assisted embolization and insertion of additional coils is considered risky [6]. Moreover, stent deployment during intracranial aneurysm coiling is reported to improve the durability of aneurysm embolization probably because of arterial wall reconstruction at the level of the neck.
stent endothelialization and change of the hemodynamics [17,20,22,32]. Nevertheless, as recurrences may still happen, radiographic follow-up is mandatory. Although digital subtraction angiography (DSA) is a standard follow-up imaging study, non-invasive and non-irradiating in nature, MR angiography (MRA) is an option [37]. It is reported that time of flight (TOF) MRA is sufficient and effective to assess re-opening of the coiled aneurysms treated using Enterprise stents, which produce more signal loss than Neuroform stents [37]. However, in patients with intracranial stents MRA cannot exactly reflect in-stent stenosis of the stented parent artery and it is suggested that DSA should be performed at least once during the follow-up period [37]. The reasons of recurrence are coil compaction or regrowth of the aneurysm [38]. The rate of recanalization after stent-assisted AcomA aneurysm embolization is 8–12% [5,6,18]. In a general population of all brain aneurysms treated with stent-assisted coiling the rate is 13–23% [13]. Recurrences are observed mainly within 6 months after treatment [17]. Risk factors for cerebral aneurysm recanalization after stented coiling are wide-necked aneurysms, partial occluded aneurysms and large or giant aneurysms [17]. Treatment options for residual or recurrent aneurysms after coil embolization include surgical clipping, re-coiling or observation [38]. There is no preferred method in this situation [38]. As the decision about retreatment is challenging, there are more or less conservative approaches among centres [6,18].

Complications

Stent-assisted coil embolization of intracranial aneurysms including AcomA aneurysms is reported to be a safe technique with low morbidity and mortality rates [5,17]. In this group the overall procedure-related complication, morbidity and mortality were 14.2%, 4.2% and 1.3%, respectively [17]. Morbidity and death rate in case of stent-assisted coiling of AcomA aneurysms is 0–5% [5,6,18].

The most frequent cause of morbidity and mortality accompanying stent-assisted coiling is thromboembolism. [17,29] According to literature, incidence of thromboembolic event in case of stent-assisted coiling ranges from 4.2 to 17.1% [17]. This complication is often clinically silent and then may be detected on a diffusion-weighted image (DWI) as a high-signal-intensity lesion (diffusion-positive lesions, i.e. DPLs) or it produces transient neurologic symptoms [17,29,39]. It is acknowledged that deploying a stent during endovascular treatment induces local thrombogenicity, especially in the acute phase of treatment before endothelialization occurs [35]. However, it is reported that adjunctive devices such as stents did not increase the thromboembolic event rate if the dual antiplatelet regimen (acetylsalicylic acid and clopidogrel) was used and the thrombocyte aggregation level was evaluated rigorously [22,40]. In three studies on stent-assisted coiling of AcomA aneurysms no symptomatic periprocedural thromboembolic events were reported, although antiplatelet strategies varied [5,6,18]. It is worth mentioning that there was one case of disabling ACA territory infarct during orthopaedic surgery, 11 months after stent-assisted embolization, in a patient who no longer took antiplatelet drugs [18]. The dual antiplatelet therapy in patients with subarachnoid hemorrhage and unprotected ruptured aneurysm is controversial. It is reported that the application of this therapy in patients who suffered from SAH worsens the prognosis if intraprocedural rupture occurs during stent embolization [35].

Delayed intra-stent (in-stent) stenosis is a rare but important complication that may be clinically significant and potentially requires additional treatment [41]. It is hypothesized that vascular remodelling (neointimal hyperplasia) as well as formation of intra-stent thrombus may be responsible for the delayed narrowing of the stented segment of the parent artery. The flexibility and radial force of the used stent also matters [17,35,41]. In three studies on stent-assisted AcomA aneurysm coiling there is only one case of in-stent stenosis [5,6,18]. The narrowing was 45% and asymptomatic. In that case the Neuroform stent was used [6]. Despite the smaller parent vessels associated with the anterior communicating complex this complication in this cohort of aneurysms was similar to previously published rates of in-stent stenosis [6].

The difference in the diameters of A1 and A2, structural characteristics of the stent (open-cell vs. closed-cell design) and angular expansion of the stented vessels (the stented A2 segment is closer to a straight line with the ipsilateral A1) may have the influence on the risk of stent migration [20].

Small AcomA or basilar apex aneurysms associated with SAH carry the highest risk of intraprocedural rupture
during coiling [42]. Perforation may occur when a coil, a microcatheter, a microguidewire or a stent is deployed [5,6,18,42]. In case of an incomplete occlusion of a perforated aneurysm, packing of additional coils is attempted to control hemorrhage [5,6,42]. Disastrous clinical outcomes occur infrequently [5,6,18,42].

Other nonspecific complications include artery dissection, groin complications, hemorrhagic incident related to anti-coagulation and SAH-related complications (vasospasm and hydrocephalus) [22].

Conclusions

Stent-assisted coil embolization of AComA aneurysms is an acknowledged treatment method with a high success rate and low procedure-related mortality-morbidity rates.
