(Dated: April 17, 2015)

The dispersive interaction of atoms and a far-detuned light field allows nondestructive imaging of the density oscillations in Bose-Einstein condensates. Starting from a ground state condensate, we investigate how the measurement back action leads to squeezing and entanglement of the quantized density oscillations. In particular, we show that properly timed, stroboscopic imaging and feedback can be used to selectively address specific eigenmodes and avoid excitation of non-targeted modes of the system.

PACS numbers: 03.75.Gg

Nonclassical, squeezed and entangled states of light provided by nonlinear optical components are important ingredients in quantum metrology and communication [1][2]. Production of analogous states of matter have been a long quest in physics with implementations demonstrated in atomic ensembles, as well as in superconducting and nanomechanical devices. Relying on nonlinearities due to atomic interactions, ultracold atoms have been prepared in two-mode entangled states of split atomic clouds [3][4] and internal state components [5][10]. Furthermore, it has been possible to prepare states that witness fundamental quantum properties through violation of inequalities obeyed by classical models [11][16].

Using dispersive light-matter interactions and measurement back action, room temperature vapour experiments have demonstrated squeezed [17] and entangled [18] states, quantum teleportation [19], and a quantum memory for light [20]. Similar experiments with interacting cold atoms and light fields have shown great progress [21][24], and numerous proposals exist [25][27] to manipulate the collective quantum states of ultracold atoms, while the full exploitation of the quantum mechanical nature of the interaction and measurements is yet to be realised.

In this Letter we develop a theoretical treatment of Bose-Einstein condensate (BEC) dynamics due to the dispersive interaction with an optical probe field, subsequently measured, and feedback [Fig. 1(a)]. Specifically, we investigate the selective preparation of squeezed and entangled states of the multimodal excitations of the BEC. Due to the temporal evolution, the local atomic density is not a quantum non-demolition (QND) variable [28][30], but by applying stroboscopic measurements at selected times, we can address effective QND variables of selected eigenmodes of the BEC dynamics.

We consider a 1D ultracold Bose gas [31] harmonically confined with axial (radial) trapping frequency $\omega_{x(\perp)}$ and the length scale $l_{x(\perp)} = \sqrt{\hbar/m\omega_{x(\perp)}}$, where radially tight confinement restricts the low energy excitations to axial motion. The BEC ground state wave function $f_0(x)$ (taken to be real) is given by the 1D Gross-Pitaevskii equation

$$[H_1 + g_{1D}n_0(x)]f_0(x) = \mu f_0(x),$$

where the BEC meanfield density is $n_0(x) = Nf_0^2(x)$, and the chemical potential, $\mu$, enforces the BEC population to the total number of atoms, $N$. $H_1$ is the single atom Hamiltonian and the 1D interaction strength is $g_{1D} = 2\hbar^2a_{sc}/ml^2_\perp$ with the s-wave scattering length $a_{sc}$.

The elementary excitations of the BEC are the collective center-of-mass, breathing, and higher order modes, where each mode, $j$, constitutes a quantum harmonic oscillator degree of freedom with (dimensionless) quadrature observables $\hat{x}_j(t)$ and $\hat{p}_j(t)$. Their frequencies, $\omega_j$, and wavefunctions, $f_j^\pm(x)$, are found by solution of the coupled Bogoliubov-de Gennes equations,

$$\begin{bmatrix}
0 & \mathcal{L}_+ \\
\mathcal{L}_- & 0
\end{bmatrix}
\begin{bmatrix}
\hat{f}_j^+(x) \\
\hat{f}_j^-(x)
\end{bmatrix} = \hbar\omega_j
\begin{bmatrix}
\hat{f}_j^+(x) \\
\hat{f}_j^-(x)
\end{bmatrix},$$

where $\mathcal{L}_\pm = H_1 - \mu + (2\pm 1)g_{1D}n_0(x)$. These eigenmodes provide an expansion of the probe atomic density,

$$\hat{n}(x,t) = n_0(x) + 2\sum_j \sqrt{n_0(x)f_j^+(x)\hat{x}_j(t)} + O(N^0),$$

embodying the dynamic quantum fluctuations about the BEC meanfield. As we shall see, stroboscopically probing the density enables mode selective squeezing [red line in Fig. 1(b)] and entanglement [heralded by nonzero off-diagonal elements in Fig. 1(c)], and realtime detection of the modes to oscillator ground states [end of Fig. 1(b)].

The dispersive light-matter interaction is characterized by the coupling constant $\kappa = -\sqrt{d_0\eta}$ with the atomic depumping rate $\eta$, and optical depth on-resonance, $d_0$ [32][33]. As we image the spatial density [1] by optical phase shift measurements [Fig. 1(a)], the light field detection in a certain pixel is sensitive to (a combination of) the atomic variables $\hat{x}_j(t)$. This is described by the atomic-pixel mode overlap integrals,

$$\bar{f}_{jd} = \int dx\int dx' \mathcal{K}_1(x-x')f_0(x')f_j^-(x'),$$
where \( \int_L dx \) denotes integration over the domain of the \( q^{th} \) pixel. The convolution with the measurement kernel \([31,32,33]\), \( K(x) = \int dke^{-(x-x')^2/2\sigma^2}e^{ikx}/2\pi\), accounts for the resolution limit along the BEC axis associated with the diffraction of light propagating over distances \( \sim 100\lambda \) through the BEC. By smearing out spatial features smaller than \( l_R = (l_\perp\lambda)^{2/3} \) where \( \lambda \) is the light wavelength, it prevents the addressing of the higher modes with shorter spatial variations (the wavelength of mode \( j \) scales as \( \sim l_\perp/j \)). We will also require, for our analysis of the correlations between modes, the atomic mode overlap integrals

\[
\bar{f}_{jk}^2 = \int dx \int dx' K_\perp(x-x')f_0(x)f_j(x)f_k(x').
\]

Since the dominant contributions of the light-matter interaction are second-order in light and atomic quadratures, and the light field is subject to quadrature measurements, the atomic quantum state can be described by a gaussian Wigner function. At all times, the state is fully characterised by \([R]_{jk} = \langle \hat{\nu}_j \rangle \) and \([A]_{jk} = \text{cov}(\hat{\nu}_j, \hat{\nu}_k)\), the first and second moments of the atomic mode variables, \( \hat{\nu} = [\hat{x}_1(t), \hat{p}_1(t), \hat{x}_2(t), \hat{p}_2(t), \ldots]^T \), respectively. Following the methodologies of \([33]\), the quantum back-action of the light field measurements of the \( \hat{p} \) quadrature in each pixel [represented by expectation values and random Wiener increments, \( dW(t) \)] results in the stochastic evolution of the first moments \([33]\).

\[
dR = -D\dot{R}dt + Am dW. \tag{2}
\]

The harmonic rotations in all \( \{\hat{x}_j(t), \hat{p}_j(t)\} \) phase spaces is represented by the block diagonal matrix, \( \mathbf{D} \), with \( 2 \times 2 \) blocks \( [\mathbf{D}]_{jk} = \begin{bmatrix} 0 & -\omega_j \\ \omega_j & 0 \end{bmatrix} \). Each pixel probes a linear combination of modes, represented by a rectangular matrix of \( 2 \times 2 \) blocks \( [\mathbf{m}]_{jd} = -\sqrt{\kappa}/\omega \begin{bmatrix} 0 & 2\kappa \bar{f}_{jd} \\ 0 & 0 \end{bmatrix} \), and owing to the correlations among the modes \( \{A\} \), the measurement results, \( d\mathbf{W} = [0, dW_1(t), 0, dW_2(t), \ldots]^T \), affect the modes in a correlated manner.

The covariance matrix (second moments) evolve as \([33]\)

\[
\dot{\mathbf{A}} = \mathbf{E} - \mathbf{D}A - AD^T - AMA, \tag{3}
\]

where \( \mathbf{M} = \mathbf{m}\mathbf{m}^T \) and the matrix \( \mathbf{E} \) with \( 2 \times 2 \) blocks, \( [\mathbf{E}]_{jk} = \begin{bmatrix} 0 & 0 \\ 0 & \kappa^2 \bar{f}_{jk}^2 \end{bmatrix} \). \( \mathbf{A} \) evolves in a manner independent of the measurement outcomes. While this implies we can deterministically assess the squeezing and entanglement properties of the system, we recall the random measurement results determine the mean displacements, about which the squeezing and entanglement occurs. We shall now first consider the covariance matrix solutions of Eq. \( \tag{3} \), focusing on the squeezing and entanglement generation, and later return to the stochastic evolution of the mean displacements described by Eq. \( \tag{2} \).

Probing with a constant optical field strength, \( \kappa \), squeezes \( \hat{x}_j(t) \) at a rate \( \nu_j = \kappa^2 \bar{f}_{jj}^2 \), while the conjugate quadrature \( \hat{p}_j(t) \) is anti-squeezed. Since \( \hat{x}_j(t) \) and \( \hat{p}_j(t) \) are coupled by rotation at rate \( \omega_j \), the squeezing may be effectively suppressed. This is reflected by Eq. \( \tag{3} \) yielding a steady state solution where the \( \hat{x}_j(t) \) variance \( \text{var}[\hat{x}_j(t)]_{ss} \approx [(1 + 4\nu_j^2)^{1/2} - 1]/2\sqrt{2}\nu_j \leq 1/2 \), and \( \nu_j \approx \nu_j/\omega_j \). Only if appreciable squeezing occurs during a fraction of a full phase space rotation, will there be squeezing in the long time limit.
For a given density, the rate of squeezing can only be increase by increasing the atomic depumping rate, \( \eta \). Alternatively, a squeezed state of an oscillator with quadrature \( \hat{x}_j(t) = \hat{x}_j^0 \cos \omega_j t + \hat{p}_j^0 \sin \omega_j t \), where the \( \hat{x}_j^0 \) quadrature is squeezed, can still be achieved by applying a temporally modulated field. Here, we implement stroboscopic probing with a sequence of constant intensity pulses determined by one or more frequencies, \( \varpi_l \). The timings, \( t_l \), and durations, \( \tau_l \), of the pulses are determined by ensuring, for each frequency, \( \varpi_l \tau_l \) is within \( \Delta \varphi / 2 \) from a multiple of \( 2\pi \). Probing at the single frequency, \( \varpi = 2\omega_j \), amounts to a train of \( n \) pulses centred on times \( t_l = [0, \pi / \omega_j, 2\pi / \omega_j, \ldots, n\pi / \omega_j] \) with identical durations, \( \tau_l = \tau = \Delta \varphi / \varpi \). Such a field addresses, and squeezes, the \( \pm \hat{x}_j^0 \) quadrature, while avoiding its anti-squeezing at intermediate times. Thus, enabling squeezing well beyond the continuous case for the same strength, \( \kappa \). For small \( \Delta \varphi \), the effective QND probing of \( \hat{x}_j^0 \) is expected, and hence, the variance of \( \hat{x}_j^0 \) for \( \tau \rightarrow n\pi / \omega_j \) is illustrated in the inset. For small \( \Delta \varphi \), the squeezing is faster but suboptimal. Excellent selectivity, Hellinger distance, \( D_H \approx 0 \), and little crosstalk, \( P \approx 1 \), are observed for small \( \Delta \varphi \). The results for the noninteracting atomic system (dotted lines) are shown for comparison.

The atomic multimodal system is far from the single mode squeezing picture. However, if no other mode, nor coupled correlation, has a rational frequency ratio to \( \omega_j \), the pulse train only addresses, and squeezes, the \( j \)th mode. This modality selectivity is illustrated in Fig. 1(b), where the variances of modes 1 and 5 are essentially unaffected during the probing of the 3rd mode. Here, the atomic interactions provide an irregular spectrum of the lowest frequency modes, allowing separate addressing without crosstalk. In light of this, evaluating the performance of squeezing and entangling operations, we will later assess the selectivity within the multimodal subspace, as well as, this subspace’s isolation from the rest of the system.

The simultaneous squeezing of two modes, \( j \) and \( k \), is achieved with the two frequencies, \( \varpi_1 = 2\omega_j \) and \( \varpi_2 = 2\omega_k \), as featured in Fig. 1(b) for modes 1 and 5 after \( \omega_j t = 25\pi / 2 \). The probing sequence is now out-of-phase with the 3rd mode, and hence, its prior squeezing is progressively lost returning to initial vacuum values. The final 5% of the trace demonstrates reinitialization of all modes to vacuum fluctuations by switching to weak continuous wave probing (\( \kappa^2 = 50\omega_j / 2\pi \)). The preservation of vacuum fluctuations of nontargeted modes, loss of squeezing of the 3rd mode, and reinitialization of all modes to vacuum fluctuations, featured in Fig. 1(b), are demonstrations of the interplay between atomic dynamics, measurement strength, and stroboscopic probing, enacting a quantum eraser for a subset of, or all, atomic modes.

To further assess the performance of the operations, we study squeezing of the 3rd mode in Fig. 2 (similar results are found for other modes and for the joint squeezing or entangling of pairs of modes). The rate of squeezing is determined by \( \Delta \varphi \), as the accumulated probing time \( \tau \rightarrow \infty \). However, only for smaller \( \Delta \varphi \), the \( x \)-quadrature is probed in a QND fashion (red line), while the squeezing for larger \( \Delta \varphi \) is suboptimal as a result of the inadvertent probing of the \( p \)-component. The figure also addresses crosstalk between the \( j = 1, 3, 5 \) subspace and its relative complement through the purity, \( P \), of the reduced system density matrix, \( \hat{\rho} \). The Hellinger distance, \( D_H = \text{Tr}[\hat{\rho}_j^2 - (\hat{\rho}_j)^2] / 2 \), quantifies the selectivity within the subset of modes. The desired state \( \hat{\rho}_d \) assumes identical \( \rho \), but with all blocks \( \{A\}_jk \), except \( j = k = 3 \), replaced by their initial vacuum values. Excellent selectivity (\( D_H \approx 0 \)) and little crosstalk (\( P \approx 1 \)) are observed for small \( \Delta \varphi \). For comparison (dotted lines), a noninteracting atomic system demonstrates similar squeezing, however, the corresponding linear spectrum \( \omega_j = \omega_{jk} \) results in significant crosstalk and poor mode selectivity.

A probe transmitted through two atomic media reveals information about their collective rather than individual properties and may hence lead to their mutual entanglement. Similarly, we may entangle two modes, \( j \) and \( k \), of a single BEC, by probing the density oscillation amplitude in a manner that does not discriminate contributions from the individual modes. The modes’ respective spatial signatures, \( \sim f_0(x) f_j^\pm(x) \) and \( \sim f_0(x) f_k^\pm(x) \), must be indistinct (\( f_j^\pm \neq 0 \)). Partial temporal distinguishability, owing to different oscillation frequencies, \( \omega_j \) and \( \omega_k \), is avoided by stroboscopically probing with a train of pulses at the single frequency, \( \varpi = \omega_j + \omega_k \).
The Gaussian multi-mode quantum state is, indeed, sub-
placements, governed by the diffusion terms in Eq. (2). In conclusion, we have demonstrated the quantum con-
trol of a matter-wave system via spatially resolved optical probing. Using stroboscopic probing and feedback, we can address and correlate effective QND observables.
of selected density modes of a BEC, while preserving the initial vacuum fluctuations of nontargeted modes. The performance of our proposal is ultimately limited by residual atomic depumping \cite{43} and by the depletion of the BEC ground state when many modes become significantly squeezed. With current experimental parameters \cite{44–46}, however, a small alkali BEC should undergo sufficient squeezing and entanglement to allow demonstration of a few-mode memory for scalable quantum information processing.
