This Version: February 19, 2019†

Abstract

Neural networks underpin many of the best-performing AI systems. Their success is largely due to their strong approximation properties, superior predictive performance, and scalability. However, a major caveat is explainability: neural networks are often perceived as black boxes that permit little insight into how predictions are being made. We tackle this issue by developing a pivotal test to assess the statistical significance of the feature variables of a neural network. We propose a gradient-based test statistic and study its asymptotics using nonparametric techniques. The limiting distribution is given by a mixture of chi-square distributions. The tests enable one to discern the impact of individual variables on the prediction of a neural network. The test statistic can be used to rank variables according to their influence. Simulation results illustrate the computational efficiency and the performance of the test. An empirical application to house price valuation highlights the behavior of the test using actual data.

†We are grateful for comments from the participants of the 2018 NeurIPS conference, the Conference on Interpretable Machine-Learning Models and Financial Applications at MIT, the Risk Seminar at ETH Zurich, the OR Seminar at UC Louvain, and the Machine Learning Conference at EPFL Lausanne. We are also grateful for discussions with Jose Blanchet, Tze Lai, and Yinyu Ye.
1 Introduction

Neural networks underpin many of the best-performing artificial-intelligence systems, including speech recognizers on smartphones or Google's latest automatic translator. The tremendous success of these applications has spurred the interest in applying neural networks in a variety of other fields. In finance and economics, for instance, researchers have developed several high-impact applications in risk management, asset pricing, and investment management. However, the difficulty of interpreting a neural network has slowed the implementation of these applications in financial practice, where regulators, investors and other stakeholders insist on model explainability.

This paper addresses the explainability of neural networks. More specifically, we develop and analyze a pivotal test to assess the statistical significance of the feature variables of a single-layer, fully connected feedforward neural network that models an unknown regression function. We construct a gradient-based test statistic that represents a weighted average of the squared partial derivative of the neural network estimator with respect to a variable. The weights are prescribed by a positive measure that can be chosen freely. We study the large-sample asymptotic behavior of the test statistic. The neural network estimator is regarded as a nonparametric sieve estimator; the dimension of the network (i.e., the number of hidden units) grows with the number of samples. Using an empirical-process approach, we first show that the large-sample asymptotic distribution of the rescaled neural network sieve estimator is given by the argmax of a Gaussian process. The Gaussian process is indexed by the function space that contains the unknown regression function. The rescaling is given by the estimation rate of the neural network identified by Chen & Shen (1998). A second-order functional delta method is then used to obtain the asymptotic distribution of the test statistic as the weighted average of the squared partial derivative of the argmax of the Gaussian process with respect to the variable of interest. The empirical test statistic, which results from a weight measure equal to the empirical law of the feature variables, has the same asymptotics. Moreover, under mild assumptions, the asymptotic distribution can be represented by a mixture of chi-square distributions. We develop several approaches to compute the limiting law; these and the performance of the test are illustrated in a simulation study. An empirical application to house price valuation in the United States complements our theoretical results and highlights the behavior of the test using actual data.

---

1 A first wave of work includes Kuan & White (1994), Lee, White & Granger (1993), Swanson & White (1997), Brown, Goetzmann & Kumar (1998), Bansal & Viswanathan (1993), Hutchinson, Lo & Poggio (1994), Desai, Crook & Overstreet Jr (1996). More recent work includes Sirignano, Sadhwani & Giesecke (2016), Sirignano (2018), Sirignano & Cont (2018), Heaton, Polson & Witte (2017), Gu, Kelly & Xiu (2018), Bühler, Gonon, Teichmann & Wood (2018), Becker, Cheridito & Jentzen (2018), Chen, Zhu & Pelger (2018).

2 See Chen (2007) for an excellent review of sieve estimation.
The significance test we propose has several desirable characteristics. First, the test procedure is computationally efficient. The partial derivative underpinning the test statistic is basically a byproduct of the widely used gradient-based fitting algorithms and is provided by standard software packages used for fitting neural networks (e.g., TensorFlow). Furthermore, the test procedure does not require re-fitting the neural network. Second, the test statistic can be used to rank order the variables according to their influence on the regression outcome. Third, the test is not susceptible to the non-identifiability of neural networks. Forth, the test facilitates model-free inference: in the large-sample asymptotic regime, due to the universal approximation property of neural networks (Hornik, Stinchcombe & White (1989)), we are performing inference on the “ground-truth” regression function. Finally, the test statistic can be extended to higher-order and cross derivatives, facilitating tests of the statistical significance of nonlinear features such as interactions between variables.

The rest of the paper is organized as follows. The remainder of the introduction discusses the related literature. Section 2 discusses the model, hypotheses and test statistic. Section 3 analyzes the large-sample asymptotic distribution of the test statistic. Section 4 provides several approaches to compute the limiting distribution. Section 5 analyzes the performance of the test in a simulation study. Section 6 develops an empirical application to house prices valuation. Section 7 concludes. There are appendices, one containing the proofs of our technical results.

1.1 Related Literature

There is prior work treating the importance and significance of variables in neural network regression models. Regarding neural networks as parametric formulations, Garson (1991), Olden & Jackson (2002), Zhang (2000) and others construct variable importance measures as functions of the network weights. However, these measures are not necessarily identifiable due to the non-identifiability of neural networks.

The large-sample asymptotic results for the estimators of neural network parameters developed by White (1989a) and White (1989b) can be used to develop significance tests for the network weights and the variables. Refenes & Zapranis (1999) construct a test statistic for variable significance whose distribution is estimated by sampling from the asymptotic distribution of the parametric neural network estimator. White & Racine (2001) develop expressions for the asymptotic distributions of two test statistics for variable significance. A bootstrap procedure is used to estimate these distributions.

Likelihood ratio tests could also be used to assess variable significance in a parametric setting. One would fit an unconstrained model incorporating all variables and nested ones.

\[3\text{Regarding identifiability, see, for example, Chen, Lu & Hecht-Nielsen (1993).}\]
with restricted variables sets. If the unconstrained model is assumed to be correctly specified, then we have standard chi-square asymptotics. Theorem 7.2 from Vuong (1989) provides the asymptotic distribution under mis-specification, a weighted sum of chi-square distributions parametrized by the eigenvalues of a \( p \times p \) matrix where \( p \) is the number of parameters of the network. While appealing, this approach tends to be computationally challenging because \( p \) is typically large and one needs to re-fit the neural network multiple times.

Alternatively, neural networks can be regarded as nonparametric models, and this is the approach we pursue. This approach has several advantages over the parametric setting considered by the aforementioned authors. First, viewing a neural network as a mapping between input variables and regression output, identifiability is no longer an issue. Moreover, by not restricting the dimension of the network (i.e., the number of hidden nodes) a priori, we can exploit the consistency of neural networks (White (1990)) which is due to their universal approximation property. Model misspecification is no longer an issue.

Nonparametric variable significance tests fall in two categories: goodness-of-fit tests or conditional moment tests; see Section 6.3 of Henderson & Parmeter (2015) for a review. Goodness-of-fit tests are based on the residuals from an unrestricted estimator fitted using all variables and the residuals from a restricted estimator fitted using all variables except the one being tested. The required distributions are either estimated using the bootstrap, or approximated asymptotically for the specific case of kernel regressions (see, for example, Gozalo (1993), Lavergne & Vuong (1996), Yatchew (1992) and Fan & Jiang (2005)). Because the tests require the estimation of a potentially large number of models, they can be computationally challenging, especially if employing the bootstrap. Conditional moment tests rely on the observation that the expectation of the residual of the restricted estimator conditional on all variables is zero under the null hypothesis of insignificance of the variables being tested. Fan & Li (1996), Lavergne & Vuong (2000), Gu, Li & Liu (2007), and others study these tests in the context of kernel regressions.

Racine (1997) proposes, again for kernel regressions, a nonparametric variable significance test based on the partial derivative of the fitted regression function with respect to a variable. The distribution of the test statistic is estimated using the bootstrap. Our test is also based on partial derivatives but we analyze a neural network regression rather than a kernel regression. Unlike Racine (1997), we study the asymptotic distribution of the test statistic in order to avoid the use of the bootstrap, which tends to be computationally expensive in the context of neural network models. The large data sets that are often used in practice to estimate neural network regressions justifies the use of the asymptotic distribution for the purpose of significance testing.
2 Model, Hypotheses, and Test Statistic

Fix a probability space \((\Omega, \mathcal{F}, \mathbb{P})\) and consider the following regression model:

\[ Y = f_0(X) + \epsilon. \]  

Here, \(Y \in \mathbb{R}\) is the dependent variable, \(X \in \mathcal{X} \subset \mathbb{R}^d\) is a vector of regressor or feature variables with distribution \(P\) for some \(d \geq 1\), and \(f_0 : \mathcal{X} \to \mathbb{R}\) is an unknown deterministic regression function that is continuously differentiable. The error variable \(\epsilon\) satisfies the usual assumptions: \(\epsilon \perp \!\!\!\perp X\), \(E(\epsilon) = 0\), and \(E(\epsilon^2) = \sigma^2 < \infty\).

We are interested in assessing the influence of a variable \(X_j\) on \(Y\). To this end, it is natural to consider the partial derivative of \(f_0(x)\) with respect to \(x_j\). If \(\frac{\partial f_0(x)}{\partial x_j} = 0\) for all \(x \in \mathcal{X}\), then the \(j\)th variable does not have an impact on \(Y\). The significance test we propose is based on the weighted average of the partial derivative, with weights defined by a positive measure \(\mu\). Specifically, we will consider the following hypotheses:

\[ H_0 : \lambda_j = \int\!\!\!\!\int_{\mathcal{X}} \left( \frac{\partial f_0(x)}{\partial x_j} \right)^2 d\mu(x) = 0 \]  
\[ H_A : \lambda_j \neq 0. \]

We take the square of the partial derivative to avoid compensation of positive and negatives values, ensure differentiability, and help discriminate between large and small values. Examples of the weight measure \(\mu\) include uniform weights, \(d\mu(x) = dx\), uniform weights over subsets \(I \subset \mathcal{X}\), \(d\mu(x) = 1_{\{x \in I\}} dx\), and the choice \(\mu = P\), where \(P\) is the distribution of \(X\). Under the latter choice, \(\lambda_j\) takes the form \(\lambda_j = E[(\frac{\partial f_0(x)}{\partial x_j})^2]\).

If the regression function \(f_0\) is assumed to be linear, i.e., \(f_0(x) = \sum_{k=1}^d \beta_k x_k\), then \(\lambda_j \propto \beta_j^2\) and the null takes the form \(H_0 : \beta_j = 0\). This hypothesis can be tested using a standard t-test. In the general non-linear case, the derivative \(\frac{\partial f_0(x)}{\partial x_j}\) is not flat but depends on \(x\). To construct the null in this case, we take a weighted average of the squared values of the derivative, with \(\mu\) prescribing the weights over the feature space \(\mathcal{X}\).

We study the case where the regression function \(f_0\) is modeled by a fully-connected, single-layer feed-forward neural network \(f\), which is specified by a bounded activation function \(\psi\) on \(\mathbb{R}\) and the number of hidden units \(K\):

\[ f(x) = b_0 + \sum_{k=1}^K b_k \psi(a_{0,k} + a_k^\top x), \]  

where \(b_0, b_k, a_{0,k}, a_k \in \mathbb{R}\) and \(a_k \in \mathbb{R}^d\) are parameters to be estimated. Functions of the form (4) are dense in \(C(\mathcal{X})\). That is, they are universal approximators: choosing the dimension \(K\) of the network large enough, \(f\) can approximate \(f_0\) to any given precision.
Let $f_n$ be an estimator of $f$ based on $n$ i.i.d. samples of $(Y, X)$. The neural network test statistic $\lambda^n_j$ associated with (2) takes the form

$$\lambda^n_j = \int_X \left( \frac{\partial f_n(x)}{\partial x_j} \right)^2 d\mu(x). \quad (5)$$

Below, we are going to study the asymptotic distribution of $\lambda^n_j$ as $n \to \infty$ under the assumption that the dimension $K = K_n$ of the neural network grows with $n$. The asymptotic distribution will be used to construct a test for the null in (2). This approach is typically less expensive computationally than a bootstrap approach. Note that in the asymptotic regime, due to the universal approximation property, we are actually performing inference on the “ground truth” $f_0$ (i.e., model-free inference).

3 Asymptotic Analysis

The neural network test statistic takes the form $\lambda^n_j = \phi[f_n]$, where $\phi$ is the functional

$$\phi[h] = \int_X \left( \frac{\partial h(x)}{\partial x_j} \right)^2 d\mu(x). \quad (6)$$

Thus, we first study the asymptotic distribution of $f_n$, and then infer the asymptotic distribution of $\lambda^n_j$ under $H_0$ from that of $f_n$ using a functional delta method.

3.1 Asymptotics of Neural Network Estimator

The unknown regression function $f_0$ is assumed to belong to the function space

$$\Theta = \left\{ f \in C^1, f : \mathcal{X} \subset \mathbb{R}^d \to \mathbb{R}, \| f \|_{1,j+2} \leq B \right\}, \quad (7)$$

where $B$ is a constant, the feature space $\mathcal{X}$ is a hypercube of dimension $d$ and

$$\| f \|_k = \sqrt{\sum_{0 \leq |\alpha| \leq k} \mathbb{E}_X (\nabla^\alpha f(X)^2)}. \quad (8)$$

We construct the neural network estimator $f_n$ as a sieved M-estimator. Given $n$ i.i.d. samples $(Y_i, X_i)_{i=1}^n$ of the output-input pair $(Y, X)$ and a nested sequence of sieve subsets $\Theta_n \subseteq \Theta$ such that $\cup_{n \in \mathbb{N}} \Theta_n$ is dense in $\Theta$, the neural network estimator $f_n$ is defined as the approximate maximizer of the empirical criterion function

$$L_{\alpha}(g) = \frac{1}{n} \sum_{i=1}^n l(Y_i, X_i, g) \quad (9)$$
with loss function $l : \mathbb{R} \times \mathcal{X} \times \Theta \to \mathbb{R}$ over the sieve space $\Theta_n$, i.e.,

$$L_n(f_n) \geq \sup_{g \in \Theta_n} L_n(g) - o_P(1). \quad (10)$$

A sieve subset $\Theta_n$ is generated by neural networks whose dimension $K = K_n$ depends on $n$ and whose activation function $\psi$ is a Lipschitz sigmoid function, i.e., a bounded measurable function on $\mathbb{R}$ such that $\psi(x) \to 1$ as $x \to \infty$ and $\psi(x) \to 0$ as $x \to -\infty$:

$$\Theta_n = \left\{ f \in \Theta : f(x) = b_0 + \sum_{k=1}^{K_n} b_k \psi(a_{0,k} + a_k^\top x), \sum_{k=0}^{K_n} |b_k| \leq c, \max_{1 \leq k \leq K_n} \sum_{i=0}^{d} |a_{i,k}| \leq \tilde{c} \right\}. \quad (11)$$

The upper bound on the norm of the weights $b_j$’s allows us to view $\Theta_n$ as the symmetric convex hull of the class of sigmoid functions $\{\psi(a^\top \cdot + a_0), a \in \mathbb{R}^d, a_0 \in \mathbb{R}\}$. It hence ensures that the integral of the metric entropy of this class of functions is bounded for every $n$ due to Theorem 2.6.9 of Vaart & Wellner (1996). The denseness of $\bigcup_{n \in \mathbb{N}} \Theta_n$ in $\Theta$ is proved in Cybenko (1989).

**Theorem 3.1 (Asymptotic distribution of neural network estimator).** Assume that

1. The law $P$ of the feature vector $X$ is absolutely continuous with respect to Lebesgue measure with bounded and strictly positive density,

2. The loss function $l(y, x, g) = -\frac{1}{2}(y - g(x))^2$,

3. The dimension $K_n$ of the neural network satisfies $K_n^{2+1/d} \log K_n = O(n)$.

Then $f_n$ converges weakly in the metric space $(\Theta, d)$ with $d(f, g) = \mathbb{E}[(f - g)^2]$: 

$$r_n(f_n - f_0) \xrightarrow{\text{w}} h^* \quad (12)$$

with 

$$r_n = \left(\frac{n}{\log n}\right)^{\frac{d+1}{2(2d+1)}} \quad (13)$$

where $h^*$ is the argmax of the Gaussian process $\{G_f : f \in \Theta\}$ with mean zero and covariance function $\text{Cov}(G_s, G_t) = 4\sigma^2 \mathbb{E}_X(s(X)t(X))$.

Theorem 3.1 derives the asymptotic distribution of the neural network estimator in a random function sense using the theory of empirical processes (Vaart & Wellner (1996)). It complements several other convergence results for neural network estimators, including the consistency result of White (1990) and results on the estimation rate and asymptotic normality of functionals of neural network estimators in Shen & Wong (1994), Shen (1997), Chen & Shen (1998) and Chen & White (1999).

\[4\] Gaussian processes on general topological spaces are treated by Adler & Taylor (2009).
3.2 Asymptotic Distribution of Test Statistic

Using Theorem 3.1, we can now derive the distribution of the test statistic under the null hypothesis using a functional delta method. A second order approach is needed since a first-order method would lead to a degenerate limiting distribution under the null.

**Theorem 3.2 (Asymptotic distribution of the test statistic).** Under the conditions of Theorem 3.1 and the null hypothesis $H_0$, we obtain:

$$r_n^2 \lambda^n_j \Rightarrow \int_X \left( \frac{\partial h^*(x)}{\partial x_j} \right)^2 d\mu(x). \quad (14)$$

In the case where the weight measure $\mu$ is equal to the law $P$ of the feature vector $X$, the test statistic takes the form

$$\lambda^n_j = \int_X \left( \frac{\partial f_n(x)}{\partial x_j} \right)^2 dP(x) = \mathbb{E}_X \left[ \left( \frac{\partial f_n(X)}{\partial x_j} \right)^2 \right] \quad (15)$$

In this case it is natural to estimate the expectation in (15) using the empirical measure $P_n$ of the samples $\{X_i\}_{i=1}^n$:

$$\hat{\lambda}_j^n = \int_X \left( \frac{\partial f_n(x)}{\partial x_j} \right)^2 dP_n(x) = n^{-1} \sum_{i=1}^n \left( \frac{\partial f_n(X_i)}{\partial x_j} \right)^2. \quad (16)$$

The following result shows that the asymptotic distribution of the empirical test statistic $\hat{\lambda}_j^n$ is the same as that of $\lambda^n_j$ (when $\mu = P$).

**Proposition 3.3 (Asymptotic distribution of the empirical test statistic).** Under the conditions of Theorem 3.2, we have:

$$r_n^2 n^{-1} \sum_{i=1}^n \left( \frac{\partial f_n(X_i)}{\partial x_j} \right)^2 \Rightarrow \mathbb{E}_X \left[ \left( \frac{\partial h^*(X)}{\partial x_j} \right)^2 \right] = \int_X \left( \frac{\partial h^*(x)}{\partial x_j} \right)^2 dP(x). \quad (17)$$

4 Computing the Asymptotic Distribution

The limiting distribution of the test statistic in Theorem 3.2 is a functional of the argmax of a Gaussian process over a function space. We discuss two approaches to computing this distribution in order to implement a test. One uses a series representation and the other a discretization method. Section 4 numerically evaluates these approaches.
4.1 Series Representation

We can exploit the fact that $\Theta$ is a subspace of the Hilbert space $L^2(P) = \{f : \mathcal{X} \to \mathbb{R} : \|f\|_{L^2(P)} < \infty\}$ which admits an orthonormal basis $\{\phi_i\}_{i=0}^\infty$. Assume that this basis is $C^1$ and is stable under differentiation. This means that $\forall i \in \mathbb{N}, 1 \leq j \leq d$, there exists an $\alpha_{i,j} \in \mathbb{R}$ and a mapping $k : \mathbb{N} \to \mathbb{N}$ such that

$$\frac{\partial \phi_i}{\partial x_j} = \alpha_{i,j} \phi_{k(i)}.$$ (18)

This, in turn, implies that there exists an invertible operator $D$ which is diagonal with respect to the basis such that

$$\|f\|^2_{k,2} = \|Df\|^2_{L^2(P)} = \sum_{i=0}^\infty d_i^2 \langle f, \phi_i \rangle^2_{L^2(P)},$$ (19)

where $d_i$'s are certain functions of the $\alpha_{i,j}$'s that satisfy

$$\sum_{i=0}^\infty \frac{1}{d_i^2} < \infty, \quad \sum_{i=0}^\infty \frac{\alpha_{i,j}^2}{d_i^4} < \infty.$$ (20)

**Theorem 4.1** (Series representation of the asymptotic distribution). Assume the conditions of Theorem 3.2 hold and that the weight measure $\mu = P$. If the orthonormal basis of $L^2(P)$ satisfies (18), then the asymptotic distribution of the test statistic satisfies

$$\mathbb{E}_X \left[ \left( \frac{\partial h^*(X)}{\partial x_j} \right)^2 \right] = \frac{B^2}{\sum_{i=0}^\infty \frac{\chi_i^2}{d_i^2} \sum_{i=0}^\infty \frac{\alpha_{i,j}^2}{d_i^4} \chi_i^2},$$ (21)

where $\{\chi_i^2\}_{i \in \mathbb{N}}$ are i.i.d. samples from the chi-square distribution.

To provide a concrete example, we consider the case where the elements of the feature vector $X$ are mutually independent and distributed uniformly on $[-1, 1]$. The density $p$ of $P$ takes the form

$$p(x) = \frac{1}{2d}.$$ (22)

We now use the Fourier basis, which is an orthonormal basis of $C^\infty$ functions for both $L^2([-1, 1]^d)$ and $\mathbb{H}^{[\frac{d}{2}]+2}([-1, 1]^d)$ with

$$\|f\|^2_{\mathbb{H}^{[\frac{d}{2}]+2}} = 2^d \sum_{n \in \mathbb{N}^d} \left[ \sum_{|\alpha| \leq \frac{d}{2}+2} \prod_{k=1}^d \gamma_n^\alpha_k \right] |f_n|^2,$$

where $\{f_n\}_{n \in \mathbb{N}^d}$ is the Fourier basis.
where \( \gamma_n = n^2 \pi^2 \), \( \phi_n^{[0]} = \cos(n \pi x) \) and \( \phi_n^{[1]} = \sin(n \pi x) \). We define the weights \( d_n^2 \) as
\[
d_n^2 = \sum_{|\alpha| \leq \lfloor \frac{d}{2} \rfloor + 2} \prod_{k=1}^{d} \gamma_{n_k}^{\alpha_k}
\]
This implies that
\[
h_\omega^* = \sum_{i \in \{0,1\}^d} \sum_{n \in \mathbb{N}^d} \frac{B}{\|D^{-1} \phi_{x}\| d_n^2 |i|^2} \phi_{n,i}^{[i]}
\]
where \( \|D^{-1} \phi_{x}\|^2 = 4 \sigma^2 \sum_{i \in \{0,1\}^d} \sum_{n \in \mathbb{N}^d} \frac{|i|^2}{d_n^2} \) and \( \{ \chi_{n,i}^{[i]} \}_{n \in \mathbb{N}^d, i \in \{0,1\}^d} \) are i.i.d. samples from a chi-square distribution. It follows that
\[
\mathbb{E}_X \left[ \left( \frac{\partial h^*(X)}{\partial x_j} \right)^2 \right] = \left\| \frac{\partial h^*(X)}{\partial x_j} \right\|_{L^2(P)}^2 = \frac{B^2}{\sum_{i \in \{0,1\}^d} \sum_{n \in \mathbb{N}^d} \chi_{n,i}^{[i]} d_n^2} \sum_{i \in \{0,1\}^d} \sum_{n \in \mathbb{N}^d} \gamma_{n,i} \chi_{n,i}^{[i]} (23)
\]

The implementation of the test requires computing a quantile of the limiting distribution. We can approximate the limiting distribution by truncating the infinite sum in Theorem 4.1 at some order \( N \), which can be chosen to achieve some given degree of accuracy. By sampling from a chi-squared distribution, we generate \( m \) samples \( \{ Z_{n,i} \}_{m,n=1}^m \) from an approximate asymptotic distribution, \( F^N \). If we let \( m \) grow along with \( N \), i.e., if we consider a sequence \( m_N \) such that \( m_N \to \infty \) as \( N \to \infty \), we obtain the consistency of the empirical approximate distribution, denoted \( F_{m_N}^N \):
\[
\text{P}_{m_N}^N(x) \xrightarrow{P_{N \to \infty}} F(x), \quad \forall x \in \mathbb{R}. \quad (25)
\]
This follows from a triangular array weak law of large number. Define the empirical approximate quantile function \( \mathbb{F}_{m_N,N}^{-1}(\alpha) \) as
\[
\mathbb{F}_{m_N,N}^{-1}(\alpha) = \frac{Z_{m_N}^N}{m_N}, \quad \text{for } \alpha \in \left( \frac{i-1}{m_N}, \frac{i}{m_N} \right] \quad (26)
\]
where \( Z_{m_N,(1)}, ..., Z_{m_N,(n)} \) are the order statistics of \( \{ Z_{i}^N \}_{i=1}^m \). Then, from the previous result and Lemma 21.2 of Van der Vaart (2000), we get the consistency of the empirical approximate quantile function:
\[
\text{P}_{m_N,N}^{-1}(\alpha) \xrightarrow{P_{N \to \infty}} F^{-1}(\alpha), \quad \forall 0 \leq \alpha \leq 1. \quad (27)
\]
Thanks to this consistent estimator, by letting the truncation order \( N \) go to infinity as \( n \to \infty \), we can reject the null if the empirical test statistic \( \hat{\lambda}_n > \mathbb{F}_{m_N,N}^{-1}(1-\alpha) \) such that the test will be asymptotically of level \( \alpha \in [0,1] \):
\[
\text{P}_{H_0}(\hat{\lambda}_n > \mathbb{F}_{m_N,N}^{-1}(1-\alpha)) \leq \alpha \quad (28)
\]
The truncation order $N$ can be chosen so as to achieve a given approximation error $\epsilon$. We illustrate this for the choice (22) discussed above. From Fourier approximation theory, we know that given the full index set of level $N$, $I_N = \{n \in \mathbb{N}^d : \max_{1 \leq j \leq d} n_j \leq N - 1\}$, the approximation rate of the Fourier series of order $N$ for any $f \in \Theta$ is:

$$
\left\| f - \sum_{i \in \{0,1\}^d} \sum_{n \in I_N} \langle f, \phi_n^{[i]} \rangle \phi_n^{[i]} \right\|_{L^2} \leq O \left( \frac{1}{N^{\frac{d}{2}+1}} \right) \quad (29)
$$

This entails that $O\left( \frac{1}{\epsilon^d} \right) \frac{1}{N^{\frac{d}{2}+2}}$ Fourier basis functions will be necessary to reach a given $L^2$ approximation error $\epsilon$.

### 4.2 Discretization Approach

The limiting distribution of the test statistic is a functional of the argmax $h^*$ of a Gaussian process indexed by the function space $\Theta$. The argmax is defined as a random function such that $\forall \omega \in \Omega$, $h^*_\omega$ satisfies $G_{h^*_\omega}(\omega) \geq G_f(\omega)$, $\forall f \in \Theta$. Given an $\epsilon$-cover $\{f_1, ..., f_C\}$ of the function space $\Theta$ of size $C$, a discrete approximation of the paths of the process can be obtained by sampling from a multivariate Gaussian variable of dimension $C$ with mean 0 and covariance matrix given by the diagonal matrix with elements $E_X(f^2_i(X))_{i=1}^C$. For every $\omega$, which corresponds to a sample from this multivariate Gaussian, the argmax among the $\epsilon$-cover can be identified and by applying the functional (6) to it, this generates an approximate sample from the limiting distribution. The accuracy is controlled by $\epsilon$.

Computing an explicit $\epsilon$-cover of the function space $\Theta$ can be challenging. A simple approach to approximate this cover uses random functions sampled from it. More specifically, we generate random neural networks (4) by sampling the network parameter. By generating a large enough number of networks, we increase the likelihood of covering $\Theta$.

### 5 Simulation Experiments

This section provides numerical results that illustrate our theoretical results and the properties of the significance test.

#### 5.1 Model

We consider a vector $X$ of eight feature variables satisfying

$$
X = (X_1, \ldots, X_8) \sim \mathcal{U}(-1, 1)^8.
$$
We consider the following data generating process:

\[ Y = 8 + X_1^2 + X_2X_3 + \cos(X_4) + \exp(X_5X_6) + 0.1X_7 + \epsilon, \]  

(30)

where \( \epsilon \sim N(0, \sigma^2) \) and \( \sigma = 0.01 \). The variable \( X_8 \) has no influence on \( Y \) and is hence irrelevant. We generate a training set of \( n = 100,000 \) independent samples and validation and testing sets of 10,000 independent samples each.

### 5.2 Fitting a Neural Network

We fit a fully-connected feed-forward neural network with one hidden layer and sigmoid activation function to the training set using the TensorFlow package. We employ the Adam stochastic optimization method with step size 0.001 and exponential decay rates for the moment estimates of 0.9 and 0.999. We use a batch size of 32, a maximum number of 150 epochs and an early stopping criterion that stops the training when the validation error has not decreased by more than \( 10^{-5} \) for at least 5 epochs. The number of hidden nodes is chosen so as to minimize the validation loss. A network with 25 hidden performs best.

Table 1 compares the neural network’s mean square error (MSE) for the test set with the test MSE for a linear model fitted to the same training data set. The neural network’s test MSE is of the order of the regression noise. The linear model’s test MSE is three orders of magnitude larger.

### 5.3 Test Statistic

For each variable \( 1 \leq j \leq 8 \), we compute the empirical test statistic \( \hat{\lambda}_j^n \) in (16) using the \texttt{gradients} function of TensorFlow. Table 2 reports the results. The statistic properly discriminates the irrelevant variable \( X_8 \) from the relevant variables. We also note that the statistic is similar for the variables that have a symmetric influence, namely \( (X_2, X_3) \) and \( (X_5, X_6) \). Moreover, for the linear variable \( X_7 \), the statistic \( \hat{\lambda}_7^n = 0.01 = 0.1^2 \), showing that the statistic correctly identifies the coefficient of \( X_7 \), which is 0.1. We note that the test statistic can be used to rank order variables according to their influence. The greater the statistic the greater the influence. Thus the quadratic variable \( X_1 \) is identified as the most important variable.
| Variable | Test Statistic | Leave-One-Out Metric |
|----------|----------------|----------------------|
| $X_1$    | 1.31           | $8.94 \cdot 10^{-2}$ |
| $X_2$    | 0.332          | $1.12 \cdot 10^{-1}$ |
| $X_3$    | 0.331          | $1.12 \cdot 10^{-1}$ |
| $X_4$    | 0.267          | $2.09 \cdot 10^{-2}$ |
| $X_5$    | 0.480          | $1.30 \cdot 10^{-1}$ |
| $X_6$    | 0.479          | $1.30 \cdot 10^{-1}$ |
| $X_7$    | $1.01 \cdot 10^{-2}$ | $3.50 \cdot 10^{-3}$ |
| $X_8$    | $4.20 \cdot 10^{-6}$ | $3.46 \cdot 10^{-6}$ |

Table 2: Values of empirical test statistic $\hat{\lambda}_j^n$ and leave-one-out metric.

For comparison, Table 2 also reports the leave-one-out metric, which is widely used in practice to assess variable influence. The leave-one-out metric for variable $X_j$ is the difference between the loss of the model based on all variables except $X_j$ and the loss of the model based on all variables. It is generally positive; the larger its value the larger one perceives the influence of a variable. The results in Table 2 suggest that the leave-one-out metric shares the symmetry properties with our test statistic. There are significant differences, however. For example, relative to our test statistic, the leave-one-out metric discounts the influence of the quadratic variable $X_1$. It identifies the exponential variables $X_5$ and $X_6$ as the most important variables. Moreover, the calculation of the leave-one-out metric requires re-fitting the model $d$ times, where $d$ is the dimension of $X$. This can be computationally expensive for models with many features. The calculation of our test statistic does not require re-fitting the model. Perhaps most importantly, our test statistic is supported by a rigorous test. To our knowledge, no test has been provided for the leave-one-out metric.

5.4 Estimation of Quantile

We choose a confidence level $\alpha = 0.05$ and compute the empirical quantile $F_{m_N,N}^{-1}(1-\alpha)$ using the series representation approach described in Section 4.1. We use the Fourier basis, choose a truncation order $N = 4$, and sample $m_N = 10,000$ observations from the corresponding approximate asymptotic distribution.

We also need to choose the constant $B$ that uniformly bounds the Sobolev norm of the functions in $\Theta$, see (7). The asymptotic distribution (24) is scaled by $B$. We need to choose $B$ large enough so that the unknown regression function $f_0$ belongs to $\Theta$, which translates to $\|f_0\|_{\frac{d}{4}+1} \leq B$. But because a $B$ that is too large would result in a test with smaller power, the optimal value of $B$ is the norm of $f_0$. One could estimate this norm using Monte Carlo
| Variable | NN Test (S) | NN Test (D) | t-Test |
|----------|-------------|-------------|--------|
| $X_1$    | 1           | 1           | 0.07   |
| $X_2$    | 1           | 1           | 0.07   |
| $X_3$    | 1           | 1           | 0.06   |
| $X_4$    | 1           | 1           | 0.05   |
| $X_5$    | 1           | 1           | 0.10   |
| $X_6$    | 1           | 1           | 0.07   |
| $X_7$    | 1           | 1           | 1      |
| $X_8$    | 0.35        | 0           | 0.04   |

Table 3: Power and size of significance tests at 5% level. The NN Test (S) column reports the values for our test using the series method to compute the asymptotic distribution of the test statistic. The NN Test (D) column reports the values for our test using the discretization method to compute the asymptotic distribution. The t-Test column reports the values for a standard $t$-test in an alternative linear regression model.

We estimate the power and size of the test by performing it on 250 alternative data sets $(Y_i, X_i)_{i=1}^n$ generated from the model (30). The second column of Table 3 reports the results. The power of the test is ideal (i.e., there is no Type 2 error). The size (Type 1 error) is 0.13, larger than the $\alpha = 0.05$ level of the test. The approximate asymptotic distribution on which the test is based might underestimate the variance of the finite sample statistic.

The last column of Table 3 also reports power and size of a $t$-test for an alternative linear regression model. Only the linear variable $X_7$ is identified as significant. These results
| Variable | Test Statistic | Leave-One-Out Metric |
|----------|----------------|----------------------|
| $X_1$    | $2 \cdot 10^{-1}\%$ | 797\%                |
| $X_2$    | $9 \cdot 10^{-2}\%$ | 572\%                |
| $X_3$    | $4 \cdot 10^{-1}\%$ | 565\%                |
| $X_4$    | $2 \cdot 10^{-1}\%$ | 2098\%               |
| $X_5$    | 58\%              | 147\%                |
| $X_6$    | 57\%              | 148\%                |
| $X_7$    | $8 \cdot 10^{-1}\%$ | 95\%                 |
| $X_8$    | 16\%              | 873\%                |

Table 4: Relative percentage change in the test statistic and leave-one-out metric (vs. values in Table 2) due to correlation of selected variables.

illustrate how model misspecification can hurt inference.

5.6 Correlated Variables

In practice, the elements of the feature vector $X$ may be correlated. We study the robustness of the test in this regard. We generate correlated variables $X_i$ whose marginal distribution is still $U(-1, 1)$ but whose correlation structure is controlled by a Gaussian copula. We first generate samples from a multivariate normal distribution $(Z_1, \ldots, Z_8) \sim \mathcal{N}(0, \Sigma)$ with covariance matrix $\Sigma$ given by

$$
\Sigma = \begin{bmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0.5 & 0 & 0 & 0 & 0 & 0 \\
0 & 0.5 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0.5 & 0 & 0 \\
0 & 0 & 0 & 0 & 0.5 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1
\end{bmatrix}
$$

implying that $X_2$ and $X_3$ as well as $X_5$ and $X_6$ are correlated. We then apply the standard normal distribution function on each coordinate to obtain the corresponding correlated uniform variables. We generate new data sets and re-fit the model.

Table 4 reports the relative percentage change in the test statistic (vs. values in Table 2). Our test statistic appears to be much more robust with respect to the correlation than the leave-one-out metric, suggesting that the test performs relatively well in the presence of correlated feature variables.
5.7 Discretization Approach

We study the performance of the significance test when using the discretization approach in Section 4.2 to estimate the asymptotic distribution. This approach approximates the argmax of the Gaussian process by using random functions sampled from \( \Theta \). More specifically, we randomly sample 500 functions using fully-connected, single-layer feed-forward neural networks with sigmoid activation function and 25 hidden units. The parameters are sampled from a Glorot normal distribution, which is a truncated normal distribution centered at 0 with standard deviation \( \sqrt{\frac{2}{\text{in} + \text{out}}} \), where \( \text{in} \) is the number of input nodes and \( \text{out} \) is the number of output nodes of the layer for which the parameters are sampled (see Glorot & Bengio (2010)).

To generate a sample from the asymptotic distribution, we first generate a sample from a multivariate normal distribution of dimension 500 with mean vector 0 and covariance matrix given by the diagonal matrix with diagonal elements equal to \( \sigma_j^2 = \frac{1}{n} \sum_{i=1}^{n} f_j(X_i)^2 \). The value \( \sigma_j^2 \) is the empirical expectation of the square of the function that we estimate. We extract the index of the maximum value from this multivariate normal, which correspond to the approximate argmax of the Gaussian process. Given this approximate argmax function, we finally generate an approximate sample from the asymptotic distribution of the test statistic. We repeat this process 10,000 times in order to estimate the quantile at the 5% level.

The third column of Table 3 reports the power and size of the test based on this approach (as before, we use 250 data sets to estimate the power and size). Our significance test has perfect power and size.

6 Empirical Application: House Price Valuation

We use the significance test to study the variables influencing house prices in the United States. We analyze a dataset of 76,247 housing transactions in California’s Merced County between 1970 and 2017. The data are obtained from the county’s registrar of deed office through the data vendor CoreLogic. The dependent variable \( Y \) of the regression is the logarithm of the sale price. The 68 elements of the feature vector \( X \) are listed in Appendix B along with descriptions. They include house characteristics, mortgage characteristics, tax characteristics, local and national economic conditions, and other types of variables. Every variable is centered and scaled to unit variance. 70% of the data is used for training, 20% for validation, and the remainder is used for testing.

We fit a fully-connected, single-layer feed-forward neural network with sigmoid activation function and \( l-1 \) regularization term using TensorFlow. We employ the Adam stochastic optimization method with step size of 0.001 and exponential decay rates for the moment
| Variable Name                  | Test Statistic |
|-------------------------------|----------------|
| Last_Sale_Amount              | 1.640          |
| Tax_Land_Square_Footage       | 1.615          |
| Sale_Month_No                 | 1.340          |
| Tax_Amount                    | 0.3834         |
| Last_Mortgage_Amount          | 0.1040         |
| Tax_Assd_Total_Value          | 0.0812         |
| Tax_Improvement_Value_Calc    | 0.0721         |
| Tax_Land_Value_Calc           | 0.0690         |
| Year_Built                    | 0.0681         |
| SqFt                          | 0.0566         |

Table 5: Test statistic for top 10 feature variables (out of 68).

estimates of 0.9 and 0.999. We use a batch size of 32, a maximum number of 100 epochs and an early stopping criterion that stops the training when the validation error has not decreased by more than $10^{-3}$ for at least 10 epochs. The number of hidden nodes and the regularization weight are chosen so as to minimize the validation loss. The optimal network architecture has 150 hidden units and the optimal regularization weight is $10^{-5}$. The mean squared error (MSE) for the test set is 0.45.

We use the discretization method to compute the asymptotic distribution of the test statistic (see Section 4.2 above). We sample 500 random functions using neural networks with the same architecture as the fitted one but with weights sampled from a Glorot normal distribution (see Section 5.7 above). 10,000 samples are generated to estimate the quantile of the asymptotic distribution.

Table 5 reports the values of the empirical test statistic (15) for the top 10 variables that are significant at the 5% level; the variables are ordered according to the magnitude of the test statistic. The last sale price is the most influential variable, closely followed by the square footage of the land. The month of sale is also very influential. This reflects the seasonality of sales: the spring months usually bring the most listings and the best sales prices, as many people try to move in the summer when the school is on break. The square footage of the home turns out to be less influential than perhaps expected.

Table 6 reports the variables that are found to be insignificant at the 5% level.
| Variable Name                                      | Test Statistic |
|---------------------------------------------------|----------------|
| Median_NonInst_PriceChange_pct                    | 4.430e-05      |
| Median_SAF_PriceChange                            | 3.096e-05      |
| Median_SAF_PriceChange_Model                      | 2.795e-05      |
| Median_NonInst_SAF_PriceChange_Model_pct          | 1.405e-05      |

Table 6: Variables that are found to be insignificant at the 5% level.

7 Conclusion

While neural networks are successfully used in many fields, they are often considered as black-box models that permit little insight into how the individual feature variables influence a prediction. We have developed and analyzed a computationally efficient, pivotal test for assessing the statistical significance of the feature variables of a single-layer, fully connected feedforward neural network that models an unknown regression function. The gradient-based test statistic represents a weighted average of the squared partial derivative of the neural network estimator with respect to a variable. Its large-sample asymptotic distribution is given by a mixture of chi-square distributions. A simulation study was used to illustrate the performance of the test and an empirical application to house price valuation was used to highlight its behavior given real data.

A Proofs

Proof of Theorem 3.1. First we consider the estimation rate \( r_n \) of \( f \) which implies the tightness of the random sequence \( h_n = r_n(f_n - f_0) \). Chen & Shen (1998) derive an estimation rate with respect to the \( L^2(P) \)-metric on \( \Theta \), \( \|f - g\|^2 = \mathbb{E}_X[(f(X) - g(X))^2] \) of the neural network sieved M-estimator, i.e. \( \|f_n - f_0\| = O_P(\frac{1}{r_n}) \) with \( K_n \) such that \( K_n^{2+1/d} \log K_n = O(n) \).

The second step is to show that a rescaled and shifted version of the empirical criterion function converges in distribution to a Gaussian process. We use a CLT for empirical processes on classes of functions changing with \( n \), see Theorem 2.11.23 of Vaart & Wellner (1996).

Using the definition of the regression problem (11), let us redefine the criterion function as \( l_g(X, \epsilon) = 2(g - f_0)(X)\epsilon - (f_0 - g)^2(X) \). We now prove a CLT for the empirical processes defined on the class of function \( \{r_n(l_{f_0+h/r_n} - l_{f_0}) : h \in K \} \) for every compact subset \( K \subset \Theta \) by using Vaart & Wellner (1996, Theorem 2.11.23). \( K \) is a compact metric space with associated metric \( \rho(s, t) = \|s - t\|_{L^2(P)} \) where \( P \) denotes the joint law of \( X \) and \( \epsilon \).
Let’s define
\[ f_{n,h} = r_n(l_{f_0+h/r_n} - l_{f_0}) = 2h(X)\epsilon - \frac{h(X)^2}{r_n} \] (31)
and the associated class of functions:
\[ \mathcal{F}_n = \{ f_{n,h} : h \in K \} \] (32)

The envelope functions \( F_n \) of \( \mathcal{F}_n \) must be such that \( \forall h \in K, f_{n,h}(x, \epsilon) \leq F_n(x, \epsilon) \), hence \( F_n \) can be chosen as \( (x, \epsilon) \rightarrow \sup_{h \in K} f_{n,h}(x, \epsilon) \). Using Chen & Shen (1998, Lemma 2), we have that \( ||h||_\infty \lesssim ||h||_2^2 \) where \( c = \frac{2}{2+d} \). Since \( K \) is a compact metric space in the \( L^2 \)-norm, it is bounded which means that \( \exists 1 < M < \infty \) such that \( \forall h \in K, ||h||_2 < M \).

Hence
\[
|f_{n,h}| \leq 2|\epsilon||h(x)| + \frac{1}{r_n}|h(x)|^2 \leq 2|\epsilon|M + \frac{1}{r_n}M^2
\]
and therefore, we can chose the envelope function as:
\[
F_n(x, \epsilon) = 2|\epsilon|M + \frac{2}{r_n}M^2
\]
where the additional factor 2 is added to simplify the computation of the metric entropy.

By definition of the envelope function and because we assume finite second moment for the regression error \( \epsilon \), we have
\[
\mathbb{E}[F_n^2(X, \epsilon)] = O(1)
\]
and
\[
\mathbb{E}(F_n^21_{\{F_n > \eta \sqrt{n}\}}) \rightarrow 0, \forall \eta > 0.
\]

Besides,
\[
(f_{n,h_1} - f_{n,h_2})^2 = \left[ \left( 2\epsilon - \frac{1}{r_n}(h_1 + h_2) \right)(h_1 - h_2) \right]^2 
\]
\[
(f_{n,h_1} - f_{n,h_2})^2 \leq \left[ \left| 2\epsilon + \frac{2}{r_n}M \right|(h_1 - h_2) \right]^2.
\]

By taking the expectation on both sides, we obtain:
\[
\mathbb{E}[(f_{n,h_1} - f_{n,h_2})^2] \lesssim \mathbb{E}[(h_1 - h_2)^2]
\]
which implies that
\[
\sup_{\rho(h_1, h_2) < \delta_n} \mathbb{E}(f_{n,h_1} - f_{n,h_2})^2 \leq O(\delta_n^2)
\]
\[
\sup_{\rho(h_1, h_2) < \delta_n} \mathbb{E}(f_{n,h_1} - f_{n,h_2})^2 \rightarrow 0, \forall \delta_n \downarrow 0
\]
Now, we need to find an upper bound on the metric entropy with bracketing of $F_n$: $N_{[]}((\epsilon\|F_n\|_{P,2}, F_n, L^2(P)))$ to be able to prove that

$$\int_0^{\delta_n} \sqrt{\log N_{[]}((\epsilon\|F_n\|_{P,2}, F_n, L^2(P)))} d\epsilon \to 0, \forall \delta_n \downarrow 0$$

To do so, we will upper bound the metric entropy with bracketing associated with $F_n$ with the metric entropy without bracketing of the initial function space $\Theta$. Indeed,

$$|f_{n,h_1} - f_{n,h_2}| = |h_1 - h_2| \left| 2\epsilon - \frac{1}{r_n} (h_1 + h_2) \right|$$

$$|f_{n,h_1} - f_{n,h_2}| \leq |h_1 - h_2| \left( 2|\epsilon| + \frac{2}{r_n} M \right) = |h_1 - h_2| |F_n(x, \epsilon)|$$

The last inequality implies that:

$$N_{[]}((\epsilon\|F_n\|_{P,2}, F_n, L^2(P))) \leq N\left( \frac{\epsilon}{2}, \Theta, \| \cdot \|_\infty \right)$$

(33)

Thanks to Nickl & Pötscher (2007, Corollary 2, Corollary 4) and because $\Theta$ as defined in (7) is a subset of the weighted Sobolev space $H^s_2(\mathbb{R}^d, \langle x \rangle^3)|\mathcal{X}$ restricted to the input space with $s = \lfloor \frac{d}{2} \rfloor + 2$, we have that:

$$\log N\left( \frac{\epsilon}{2}, \Theta, \| \cdot \|_\infty \right) \lesssim \left( \frac{1}{\epsilon} \right)^{-\frac{d}{4}}$$

(34)

By combining (33) and (34), we have that

$$\int_0^1 \sqrt{\log N_{[]}((\epsilon\|F_n\|_{P,2}, F_n, L^2(P)))} d\epsilon < \infty$$

for all $n$ which implies that

$$\int_0^{\delta_n} \sqrt{\log N_{[]}((\epsilon\|F_n\|_{P,2}, F_n, L^2(P)))} d\epsilon \to 0, \forall \delta_n \downarrow 0$$

Now, we want to show that the sequence of covariance functions $Pf_{n,s}f_{n,t} - Pf_{n,s}Pf_{n,t}$ converges pointwise on $\Theta \times \Theta$.

$$Pf_{n,s}Pf_{n,t} = \mathbb{E} \left[ 2s(X) \epsilon - \frac{s(X)^2}{r_n} \right] \mathbb{E} \left[ 2t(X) \epsilon - \frac{t(X)^2}{r_n} \right] \to 0$$
as \( n \to \infty \) and
\[
P_{f_n,s_n,t} = \mathbb{E} \left[ \left( 2s(X)\epsilon - \frac{s(X)^2}{r_n} \right) \left( 2t(X)\epsilon - \frac{t(X)^2}{r_n} \right) \right] \to 4\sigma^2 \mathbb{E}(s(X)t(X))
\]
hence the sequence of covariance functions converges pointwise to \( 4\sigma^2 \mathbb{E}(s(X)t(X)) \).

Hence, since all the hypothesis of Theorem Vaart & Wellner (1996, Theorem 2.11.23) are satisfied, we have that the sequence of empirical processes \( \{ \mathcal{G}_{n,f_n,h} : h \in K \} \) is asymptotically tight in \( l^\infty(K) \) and converges in distribution to a tight mean zero Gaussian process \( \mathcal{G} \) with covariance \( 4\sigma^2 \mathbb{E}(s(X)t(X)) \).

We now need to show that all sample paths \( h \to \mathcal{G}(h) \) are upper semi continuous and that the limiting Gaussian process \( \{ \mathcal{G}_f : f \in \Theta \} \) has a unique maximum at a random function \( h^* \).

Let’s first note that the space \( \Theta \) is \( || \cdot ||_{L^2(P)} \)-compact as shown in Freyberger & Masten (2015).

Concerning continuity of the sample paths of the Gaussian process, as stated in Adler (1990, Corollary 4.15), a sufficient condition of continuity of a centered Gaussian process with an index space \( \Theta \) totally bounded with respect to the canonical metric \( d \) induced by the process, \( d(s,t) = \sqrt{\mathbb{E}[(\mathcal{G}_s - \mathcal{G}_t)^2]} \), is that
\[
\int_0^\infty \sqrt{\log N(\epsilon, \Theta, d)} d\epsilon < \infty.
\]

Let’s note that in our case the canonical metric induced by the process \( d \) is proportional to the regular \( || \cdot ||_{L^2(P)} \) metric:
\[
d(s,t) = \sqrt{\mathbb{E}[(\mathcal{G}_s - \mathcal{G}_t)^2]}
\]
\[
d(s,t) = \sqrt{\mathbb{E}[\mathcal{G}_s^2] + \mathbb{E}[\mathcal{G}_t^2] - 2\mathbb{E}[\mathcal{G}_s \mathcal{G}_t]}
\]
\[
d(s,t) = \sqrt{4\sigma^2 \mathbb{E}[s^2] + 4\sigma^2 \mathbb{E}[t^2] - 8\sigma^2 \mathbb{E}[st]}
\]
\[
d(s,t) = 2\sigma ||s - t||_{L^2(P)}.
\]

Therefore we need to show that
\[
\log N(\epsilon, \Theta, L^2(P)) \preceq \left( \frac{1}{\epsilon} \right)^{\alpha}
\]
with \( \alpha < 2 \). This can also be proved thanks to Nickl & Pötscher (2007, Corollary 2, Corollary 4) and by definition of \( \Theta \) in (7).
This proves the boundedness of the integral of the metric entropy defined under the \( d \) metric. The total boundedness of the index space \( \Theta \) is induced by its compactness. Hence \( \{ G_f : f \in \Theta \} \) is continuous over a compact index space which implies that \( \{ G_f : f \in \Theta \} \) reaches its maximum.

Uniqueness of the maximum of a Gaussian process is given in Kim & Pollard (1990, Lemma 2.6) and requires continuity of sample paths, a compact index space and for every \( s \neq t, \text{Var}(G_s - G_t) \neq 0 \). This is satisfied in our case, indeed, \( \text{Var}(G_s - G_t) = 4\sigma^2\mathbb{E}(s^2 + t^2) - 8\sigma^2\mathbb{E}(st) = 4\sigma^2\mathbb{E}((s-t)^2) \neq 0 \).

Finally, from the convergence of the empirical criterion function and the tightness of the random sequence \( h_n \) previously shown, one can apply the argmax continuous mapping theorem as stated in Vaart & Wellner (1996, Theorem 3.2.2), to prove the convergence of \( h_n \) to the argmax of the Gaussian process \( h^* \), which finishes the proof. \( \square \)

**Proof of Theorem 3.2.** The result follows from Theorem 3.1 and the second order functional delta method Rönnisch (2005, Theorem 2). We need to compute the Hadamard derivative of our functional of interest \( \phi \) as defined in (30). The second-order Hadamard directional derivative of a mapping between two normed space \( D \) and \( F \), \( \phi : D_0 \subseteq D \rightarrow F \) at \( \theta_0 \) in the direction \( h \) tangential to \( D_0 \) is defined as:

\[
\phi''_{\theta_0}(h) = \lim_{t \to 0, n \to \infty} \frac{\phi(\theta_0 + th_n) - \phi(\theta_0) - t\phi'_{\theta_0}(h_n)}{\frac{1}{2}t^2}
\]

for every sequence \( h_n \to h \) such that \( \theta_0 + th_n \) is contained in the domain of \( \phi \) for all small \( t \).

In our case, the second derivative of \( \phi \) at \( \theta_0 \) under the null hypothesis is equal to:

\[
\phi''_{\theta_0}(h) = 2\int_X \left( \frac{\partial h(x)}{\partial x_j} \right)^2 d\mu(x).
\]

(36)

This completes the proof. \( \square \)

**Proof of Proposition 3.3.** We simplify the notation as

\[
\hat{\lambda}_j^n = \mathbb{P}_n \eta(f_n), \quad \lambda_j^n = P \eta(f_n)
\]

where \( P \) and \( \mathbb{P}_n \) denote the expectation and the empirical expectation respectively, and

\[
\eta(f) = \left( \frac{\partial f}{\partial x_j} \right)^2.
\]

We can decompose \( r_n^2 \left( \mathbb{P}_n \eta(f_n) - P \eta(f_0) \right) \) as

\[
r_n^2 \left( \mathbb{P}_n \eta(f_n) - P \eta(f_0) \right) = \frac{r_n^2}{\sqrt{n}} \mathbb{G}_n \left( \eta(f_n) - \eta(f_0) \right) + \frac{r_n^2}{\sqrt{n}} \mathbb{G}_n \left( \eta(f_0) \right) + r_n^2 \left( P \eta(f_n) - P \eta(f_0) \right)
\]

(37)
where $G_n$ denotes the empirical process operator defined as $G_n f = \sqrt{n}(\mathbb{P}_n - P f)$.

By definition of $r_n$ in (13), it is a $o(n^{1/4})$ so we have that $\frac{r^2_n}{\sqrt{n}} = o(1)$. By CLT, $G_n \left( \eta(\theta_0) \right)$ converges in distribution to $N(0, \text{Var} \left[ (\frac{\partial h}{\partial x_j})^2(X) \right])$ which is equal to 0 under the null. The distribution of the last term $r^2_n \left( P \eta(f_n) - P \eta(f_0) \right)$ is given by Theorem 3.2.

For the remaining term, we show that the empirical process $\{G_n f_{n,h} : h \in K\}$ based on the family of functions $\{f_{n,h} = \eta(\theta_0 + h/r_n) - \eta(\theta_0), h \in K\}$ converges to a tight Gaussian process using Vaart & Wellner (1996, Theorem 2.11.23).

For the remaining term, we show that the empirical process $\{G_n f_{n,h} : h \in K\}$ based on the family of functions $\{f_{n,h} = \eta(\theta_0 + h/r_n) - \eta(\theta_0), h \in K\}$ converges to a tight Gaussian process using Vaart & Wellner (1996, Theorem 2.11.23).

\[ f_{n,h} = \eta(\theta_0 + h/r_n) - \eta(\theta_0) = \frac{1}{r_n^2} \left( \frac{\partial h}{\partial x_j} \right)^2 \] (38)

under the null hypothesis. By definition of $\Theta$, $\exists M > 0$ such that $\forall h \in \Theta$, $\left\| \frac{\partial h}{\partial x_j} \right\| \leq M$. Because $\frac{\partial h}{\partial x_j}$ is $C^1$ and by Chen & Shen (1998, Lemma 2), we have a uniform boundedness with the infinity norm, i.e. $\exists M > 0$ such that $\forall h \in K$, $\left\| \frac{\partial h}{\partial x_j} \right\|_\infty \leq M$.

We can then define the envelope function $F_n$ as

\[ F_n(x) = \frac{2M}{r_n^2} \] (39)

This satisfies:

\[ \mathbb{E}(F_n^2) = O(1), \]

\[ \mathbb{E}(F_n^2 \mathbb{1}_{\{F_n > \eta \sqrt{n} \}}) \to 0 \]

for every $\eta > 0$.

\[ f_{n,s} - f_{n,t} = \frac{1}{r_n^2} \left[ \left( \frac{\partial s}{\partial x_j} \right)^2 - \left( \frac{\partial t}{\partial x_j} \right)^2 \right] \to 0 \text{ for all } s, t \in \Theta \times \Theta \]

we immediately have that:

\[ \sup_{\rho(s,t) < \delta_n} \mathbb{E}|(f_{n,s} - f_{n,t})^2| \to 0 \]

for every $\delta_n \to 0$.

\[ |f_{n,s} - f_{n,t}| \leq \frac{1}{r_n^2} \left[ \left( \frac{\partial s}{\partial x_j} \right)^2 - \left( \frac{\partial t}{\partial x_j} \right)^2 \right] \]

\[ |f_{n,s} - f_{n,t}| \leq |F_n(x)| \left| \frac{\partial s}{\partial x_j} - \frac{\partial t}{\partial x_j} \right| \]

Hence by using the same argument as in the proof of Theorem 3.1, we obtain:

\[ N_\mathbb{I}(\epsilon ||F_n||_{P,2}, \mathcal{F}_n, L^2(P)) \leq N \left( \frac{\epsilon}{2}, \Theta', \| \cdot \|_\infty \right) \] (40)
where $\Theta' = \{ \frac{\partial f}{\partial x_j} : f \in \Theta \}$.

By definition of $\Theta$ and thanks to Nickl & Pötscher (2007, Corollary 2 and 4) we have that

$$\log N([\epsilon||F_n||_{P_2, F_n, L^2(P)}] \lesssim \left( \frac{1}{\epsilon} \right)^\gamma$$

with $\gamma < 2$.

This last condition ensures that:

$$\int_0^{\delta_n} \sqrt{\log N([\epsilon||F_n||_{P_2, F_n, L^2(P)}])} d\epsilon \to 0, \forall \delta_n \downarrow 0$$

By Vaart & Wellner (1996, Theorem 2.11.23), we obtain that $G_n(\eta(\hat{\theta}_n) - \eta(\theta_0))$ is asymptotically tight.

Then, $\frac{n}{\sqrt{n}} G_n(\eta(\hat{\theta}_n) - \eta(\theta_0))$ converges to 0 in probability. By Slutsky’s theorem, we finally get that the limiting distribution of $\hat{\lambda}_j^n$ is the same as the one of $\lambda_j^n$.

**Proof of Theorem 4.1.** Recall that in our case, the limiting Gaussian process is centered and has covariance $\text{Cov}(G_f, G_g) = 4\sigma^2 \mathbb{E}(fg)$, which is the scaled inner product $\langle f, g \rangle = \mathbb{E}(fg)$ in the Hilbert space $L^2(P)$. If we consider an orthonormal basis $\{\phi_i\}_{i=1}^\infty$ of the Hilbert space, then $f = \sum_{i=1}^\infty \langle f, \phi_i \rangle \phi_i, \forall f \in \Theta$.

By linearity of the Gaussian process, we have that:

$G_f = \sum_{i=1}^\infty \langle f, \phi_i \rangle G_{\phi_i}.$

(41)

The linearity of $G$ is proved as follows: $G_{f+\lambda g} \sim \mathcal{N}(0, 4\sigma^2 \mathbb{E}(f + \lambda g)^2)$ by definition of $G$ and $G_f + \lambda G_g \sim \mathcal{N}(0, 4\sigma^2 \mathbb{E}[f^2] + \lambda^2 4\sigma^2 \mathbb{E}[g^2] + 2\lambda 8\sigma^2 \mathbb{E}(fg))$, hence $G_{f+\lambda g}$ and $G_f + \lambda G_g$ are equal in distribution.

Because $\{\phi_i\}_{i=1}^\infty$ is an orthonormal basis,

$G_{\phi_i} \sim \mathcal{N}(0, 4\sigma^2)$

(42)

and $\forall i \neq j$, we have $\text{Cov}(G_{\phi_i}, G_{\phi_j}) = 0$. This, combined with the fact that $G_{\phi_i}$ and $G_{\phi_j}$ are jointly normal, implies that $G_{\phi_i}$ is independent of $G_{\phi_j}$.

Hence, by combining (41) and (42), we obtain the following decomposition of the Gaussian process $\forall f \in \Theta$:

$$\sum_{i=1}^\infty \langle f, \phi_i \rangle \xi_i$$

(43)

where $\{\xi_i\}_{i=1}^\infty$ is an infinite sequence of independent normal variables such that $\xi_i \sim \mathcal{N}(0, 4\sigma^2)$. 24
Our objective is to estimate the distribution of the argmax \( h^* \) of the previous Gaussian process. The argmax is defined as a random function \( \Omega \to \Theta \) such that \( \forall \omega \in \Omega, h^* \) satisfies \( \mathbb{G}_{h^*}(\omega) \geq \mathbb{G}_f(\omega), \forall f \in \Theta \). The previous expansion of the Gaussian process gives us one way to compute the argmax for each \( \omega \). Indeed, for every \( \omega \in \Omega \) which corresponds to a sample from the infinite sequence of independent normal variables \( \{\xi_i\}_{i=1}^{\infty} \), let’s define \( \Phi_{\xi}: \Theta \to \mathbb{R} \) as \( \Phi_{\xi}(f) = \mathbb{G}_f(\omega) = \sum_{i=1}^{\infty} \langle f, \phi_i \rangle \xi_i \). \( \Phi_{\xi} \) is a bounded linear functional on the Hilbert space \( L^2(P) \), hence by Riesz representation theorem, \( \exists \phi_{\xi} \in L^2(P) \) such that \( \mathbb{G}_f(\omega) = \langle f, \phi_{\xi} \rangle_{L^2(P)} \). Hence, finding \( f \in \Theta \) that maximizes \( \mathbb{G}_f(\omega) \) is equivalent of finding \( f \in \Theta \) that maximizes the inner product \( \langle f, \phi_{\xi} \rangle_{L^2(P)} \).

By associating to any \( f \in L^2(P) \) its corresponding infinite sequence \( \{\langle f, \phi_i \rangle\}_{i \in \mathbb{N}} \), one can identify \( L^2(P) \) with the \( l^2 \) space of infinite sequences with bounded 2-norm. Hence, (19) shows that the Sobolev norm \( \| \cdot \|_{H^k(P)} \) is a weighted version of the \( l^2 \) norm with weights \( d_i^2 \).

Thanks to the previous observation, finding \( f \in \Theta \) that maximizes \( \mathbb{G}_f(\omega) \) can be re-expressed as solving the following optimization problem:

\[
\max_{\{\langle f, \phi_i \rangle\}_{i \in \mathbb{N}}} \langle f, \phi_{\xi} \rangle_{L^2(P)} = \sum_{i=0}^{\infty} \langle f, \phi_i \rangle \langle \phi_{\xi}, \phi_i \rangle
\]

subject to \( \|Df\|_{l^2}^2 = \sum_{i=0}^{\infty} d_i^2 \langle f, \phi_i \rangle^2 \leq B \).

By defining \( g = Df \), the optimization problem above can be reformulated as:

\[
\max_{g} \langle g, D^{-1} \phi_{\xi} \rangle_{l^2}
\]

subject to \( \|g\|_{l^2} \leq B \) whose solution by Cauchy-Schwartz inequality obviously is:

\[
g^* = \frac{B}{\|D^{-1} \phi_{\xi}\|_{L^2(P)}} D^{-1} \phi_{\xi}.
\]

Because \( f = D^{-1}g \) and \( \phi_{\xi} = \sum_{i=0}^{\infty} \xi_i \phi_i \), the argmax can be computed explicitly as:

\[
h^*_\omega = \sum_{i=0}^{\infty} \frac{B}{\|D^{-1} \phi_{\xi}\|} \frac{\xi_i}{d_i^2} \phi_i
\]

where \( \|D^{-1} \phi_{\xi}\|^2 = 4\sigma^2 \sum_{i=0}^{\infty} \frac{\chi_i^2}{d_i^4} \) and \( \{\chi_i^2\}_{i \in \mathbb{N}} \) are i.i.d. samples from a chi-square distribution.

Given the argmax \( h^* \) and because of (18), we can compute the associated statistic:

\[
\mathbb{E}_X \left( \frac{\partial h^*(X)}{\partial x_j} \right)^2 = \left\| \frac{\partial h^*(X)}{\partial x_j} \right\|_{L^2(P)}^2 = \frac{B^2}{\sum_{i=0}^{\infty} \frac{\chi_i^2}{d_i^4}} \sum_{i=0}^{\infty} \frac{\alpha_{i,j}^2}{d_i^4} \chi_i^2.
\]

\[
\square
\]

**Zip-code Variables**
| Variable                                    | Description                                                                 |
|---------------------------------------------|-----------------------------------------------------------------------------|
| N_ShortSales                                | Number of short sales that occurred within the same zipcode as the property within the past 12 months. |
| N_PrePayments                               | Number of loans that have been prepaid                                      |
| N_Outstanding_Loans                         | How many loans are currently outstanding                                    |
| N_PIF                                       | Number of loans that were paid in full by reaching their term maturity      |
| N_Originations                              | Number of loans originated at same location and same time period of sale    |
| Median_Time_to_SAF                          | Median time between the original foreclosure month and the SAF month of all SAF that occurred in the given month. |
| Median_Time_to_NonInst_SAF                  | Same as above but for non-institutional / non-corporate owner SAF.         |
| Median_Time_to_SAF_l12                      | Same as above except that computation rolls over the 12 preceding months.  |
| Median_Time_to_NonInst_SAF_l12              | Same as above except that computation rolls over the 12 preceding months.  |
| Median_time_since_foreclosure_SAF           | Median time between the current month and when the foreclosure originally occurred of all properties that have already been foreclosed upon but have not yet been sold. |
| Median_time_since_foreclosure_NonInst_SAF   | Same as above but for non-institutional / non-corporate owner sales after foreclosure. |
| Median_SAF_PriceChange                      | Median difference between price of the SAF and last recorded sale price of the property for all SAF that occurred in current month. |
| Median_NonInst_PriceChange                  | Same as above but for non-institutional / non-corporate owner SAF.         |
| Median_SAF_PriceChange_l12                  | Same as above except that computation rolls over the 12 preceding months.  |
| Median_NonInst_PriceChange_l12              | Same as above except that computation rolls over the 12 preceding months.  |
| Median_SAF_PriceChange_pct                  | Same as above except that the price change is expressed as a percentage, i.e. the price change divided by the previous sale price. |
| Median_NonInst_PriceChange_pct              | Same as above except that the price change is expressed as a percentage.  |
Median SAF PriceChange pct l12
Same as above except that the price change is expressed as a percentage.

Median NonInst PriceChange pct l12
Same as above except that the price change is expressed as a percentage.

Median SAF PriceChange Model
Median difference between price of the SAF and a modeled sale price of the property (last sale price * [1 + zip code level House Price Index percent change since last sale]) for all SAF that occurred in current month.

Median NonInst PriceChange Model
Same as above but for non-institutional / non-corporate owner SAF.

Median SAF PriceChange Model l12
Same as above except that computation rolls over the 12 preceding months.

Median NonInst PriceChange Model l12
Same as above except that computation rolls over the 12 preceding months.

Median SAF PriceChange Model pct
Same as above except that the price change is expressed as a percentage, i.e. the price change divided by the previous sale price.

Median SAF PriceChange Model pct l12
Same as above except that the price change is expressed as a percentage.

Median NonInst SAF PriceChange Model pct
Same as above except that the price change is expressed as a percentage.

Median NonInst SAF PriceChange Model pct l12
Same as above except that the price change is expressed as a percentage.

Time to NonInst to Outstanding Loans
Ratio of Median Time to NonInst SAF l12 variable over N Outstanding Loans
