Abstract. This work examines strategies to handle large shared data objects in distributed storage systems (DSS), while boosting the number of concurrent accesses, maintaining strong consistency guarantees, and ensuring good operation performance. To this respect, we define the notion of fragmented objects: concurrent objects composed of a list of fragments (or blocks) that allow operations to manipulate each of their fragments individually. As the fragments belong to the same object, it is not enough that each fragment is linearizable to have useful consistency guarantees in the composed object. Hence, we capture the consistency semantic of the whole object with the notion of fragmented linearizability. Then, considering that a variance of linearizability, coverability, is more suited for versioned objects like files, we provide an implementation of a distributed file system, called C\textsuperscript{OB}FS, that utilizes coverable fragmented objects (i.e., files). Preliminary emulation of C\textsuperscript{OB}FS demonstrates the potential of our approach in boosting the concurrency of strongly consistent large objects.

Keywords: Distributed storage · Large objects · Linearizability · Coverability.

1 Introduction

In this paper we deal with the storage and use of shared readable and writable data in unreliable distributed systems. Distributed systems are subject to perturbations, which may include failures (e.g., crashes) of individual computers, or delays in processing or communication. In such settings, large (in size) objects are difficult to handle. Even more challenging is to provide linearizable consistency guarantees to such objects.

Researchers usually break large objects into smaller linearizable building blocks, with their composition yielding the complete consistent large object. For example, a linearizable shared R/W memory is composed of a set of linearizable shared R/W objects [2]. By design, those building blocks are usually independent, in the sense that

\* Supported by the Cyprus Research and Innovation Foundation under the grant agreement POST-DOC/0916/0090.
changing the value of one does not affect the operations performed on the others, and that operations on the composed objects are defined in terms of operations invoked on the (smallest possible) building blocks. Operations on individual linearizable registers do not violate the consistency of the larger composed linearizable memory space.

Some large objects, however, cannot be decomposed into independent building blocks. For example, a file object can be divided into fragments or blocks, so that write operations (which are still issued on the whole file) modify individual fragments. However, the composition of these fragments does not yield a linearizable file object: it is unclear how to order writes on the file when those are applied on different blocks concurrently. At the same time, it is practically inefficient to handle large objects as single objects and use traditional algorithms (like the one in [2]) to distribute it consistently.

**Related work:** Attiya, Bar-Noy and Dolev [2], proposed an algorithm, colloquially referred to as ABD, that emulates a distributed shared R/W register in message-passing, crash-prone, asynchronous environments. To ensure availability, the object is replicated among a set of servers and to provide operation ordering, a logical timestamp is associated with each written value. ABD tolerates replica server crashes, provided a majority of servers do not fail. Write operations involve a single communication round-trip. The writer broadcasts its request to all servers and it terminates once it collects acknowledgments from some majority of servers. A read involves two round-trips. In the first, the reader broadcasts a request to all servers, collects acknowledgments from some majority of servers, and it discovers the maximum timestamp. To ensure that any subsequent read will return a value associated with a timestamp at least as high as the discovered maximum, the reader propagates the value associated with the maximum timestamp to at least a majority of servers before completion, forming the second round-trip. ABD was later extended for the multi-writer/multi-reader model in [21], and its performance was later improved by several works, including [11,16,17,13,15]. Those solutions considered small objects, and relied on the dissemination of the object values in each operation, imposing a performance overhead when dealing with large objects.

Fan and Lynch [12] attempted to reduce performance overheads by separating the metadata of large objects from their value. In this way, communication-demanding operations were performed on the metadata, and large objects were transmitted to a limited number of hosts, and only when it was “safe” to do so. Although this work improved the latency of operations, compared to traditional approaches like [2,21], it still required to transmit the entire large object over the network per read and write operation. Moreover, if two concurrent write operations affected different “parts” of the object, only one of them would prevail, despite updates not being directly “conflicting.”

Recently, Erasure-Coded (EC) approaches have gained momentum and have proved being extremely effective in saving storage and communication costs, while maintaining strong consistency and fault-tolerance [6,7,10,19,20,8,28,23]. EC approaches rely on the division of a shared object into coded blocks and deliver a single block to each data server. While very appealing for handling large objects, they face the challenge of efficiently encoding/decoding data. Despite being subdivided into several fragments, reads and writes are still applied on the entire object value. Therefore, multiple writers cannot work simultaneously on different parts of an object.
Value continuity is important when considering large objects, oftentimes overseen by distributed shared object implementations. In files, for example, a write operation should extend the latest written version of the object, and not overwrite any new value. Coverability was introduced in [24] as a consistency guarantee that extends linearizability and concerns versioned objects. An implementation of a coverable (versioned) object was presented, where ABD-like reads return both the version and the value of the object. Writes, on the other hand, attempt to write a “versioned” value on the object. If the reported version is older than the latest, then the write does not take effect and it is converted into a read operation, preventing overwriting a newer version of the object.

Contributions: In this work we set the goal to study and formally define the consistency guarantees we can provide when fragmenting a large R/W object into smaller objects (blocks), so that operations are still issued on the former but are applied on the latter. In particular, the contributions of this paper are as follows:

– We define two types of concurrent objects: (i) the block object, and (ii) the fragmented object. Blocks are treated as R/W objects, while fragmented objects are defined as lists of block objects (Section 3).

– We examine the consistency properties when allowing R/W operations on individual blocks of the fragmented object, in order to enable concurrent modifications. Assuming that each block is linearizable, we define the precise consistency that the fragmented object provides, termed Fragmented Linearizability (Section 4).

– We provide an algorithm that implements coverable fragmented objects. Then, we use it to build a prototype implementation of a distributed file system, called CoBFS, by representing each file as a linked-list of coverable block objects. CoBFS adopts a modular architecture, separating the object fragmentation process from the shared memory service, which allows to follow different fragmentation strategies and shared memory implementations. We show that CoBFS preserves the validity of the fragmented object and satisfies fragmented coverability (Section 5).

– We describe an experimental development and deployment of CoBFS on the Emulab testbed [1]. Preliminary results are presented, comparing our proposed algorithm to its non-fragmented counterpart. Results suggest that a fragmented object implementation boosts concurrency while reducing the latency of operations (Section 6).

2 Model

We are concerned with the implementations of highly-available replicated concurrent objects that support a set of operations. The system is a collection of crash-prone, asynchronous processors with unique identifiers (ids) from a totally-ordered set \( \mathcal{I} \), composed of two main disjoint sets of processes: (a) a set \( \mathcal{C} \) of client processes ids that may perform operations on a replicated object, and (b) a set \( \mathcal{S} \) of server processes ids that each holds a replica of the object. Let \( \mathcal{I} = \mathcal{C} \cup \mathcal{S} \).

Processors communicate by exchanging messages via asynchronous point-to-point reliable[4] channels; messages may be reordered. Any subset of client processes and up to a minority of servers (less than \( |\mathcal{S}|/2 \)), may crash at any time in an execution.

[4] Reliability is not necessary for the correctness of the algorithms we present. It is just used for simplicity of presentation.
Executions, histories and operations: An execution $\xi$ of a distributed algorithm $A$ is an alternating sequence of states and actions of $A$ reflecting the evolution in real time of the execution. A history $H_\xi$ is the subsequence of the actions in $\xi$. We say that an operation $\pi$ is invoked (starts) in an execution $\xi$ when the invocation action of $\pi$ appears in $H_\xi$, and $\pi$ responds to the environment (ends or completes) when the response action appears in $H_\xi$. An operation is complete in $\xi$ when both its invocation and matching response actions appear in $H_\xi$ in that order. A history $H_\xi$ is sequential if it starts with an invocation action and each invocation is immediately followed by its matching response; otherwise, $H_\xi$ is concurrent. Finally, $H_\xi$ is complete if every invocation in $H_\xi$ has a matching response in $H_\xi$ (i.e., each operation in $\xi$ is complete).

We say that an operation $\pi$ precedes in real time an operation $\pi'$ (or $\pi'$ succeeds in real time $\pi$) in an execution $\xi$, denoted by $\pi \rightarrow \pi'$, if the response of $\pi'$ appears before the invocation of $\pi'$ in $H_\xi$. Two operations are concurrent if neither precedes the other.

Consistency: We consider linearizable R/W objects. A complete history $H_\xi$ is linearizable if there exists some total order on the operations in $H_\xi$ that respects the real-time order $\rightarrow$ of operations, and is consistent with the semantics of operations.

Note that we use read and write in an abstract way: (i) write represents any operation that changes the state of the object, and (ii) read any operation that returns that state.

## 3 Fragmented Objects

A fragmented object is a concurrent object (e.g., can be accessed concurrently by multiple processes) that is composed of a finite list of blocks. Section 3.1 formally defines the notion of a block, and Section 3.2 gives the formal definition of a fragmented object.

### 3.1 Block Object

A block $b$ is a concurrent R/W object with a unique identifier from a set $B$. A block has a value $\text{val}(b) \in \Sigma^*$, extracted from an alphabet $\Sigma$. For performance reasons it is convenient to bound the block length. Hence, we denote by $B^\ell \subset B$, the set that contains bounded length blocks, s.t. $\forall b \in B^\ell$ the length of $\text{val}(b) \leq \ell$. We use $|b|$ to denote the length of the value of $b$ when convenient. An empty block is a block $b$ whose value is the empty string $\varepsilon$, i.e., $|b| = 0$. Operation create($b$, $D$) is used to introduce a new block $b \in B^\ell$, initialized with value $D$, such that $|D| \leq \ell$. Once created, block $b$ supports the following two operations: (i) read($b$) that returns the value of the object $b$, and (ii) write($D$)$_b$ that sets the value of the object $b$ to $D$, where $|D| \leq \ell$.

A block object is linearizable if it satisfies the linearizability properties with respect to its create (which acts as a write), read, and write operations. Once created, a block object is an atomic register whose value cannot exceed a predefined length $\ell$.

### 3.2 Fragmented Object

A fragmented object $f$ is a concurrent R/W object with a unique identifier from a set $F$. Essentially, a fragmented object is a sequence of blocks from $B$, with a value $\text{val}(f) = \langle b_0, b_1, \ldots, b_n \rangle$, where $b_i \in B$, for $i \in [0, n]$. Initially, each fragmented object contains
 Fragmented Objects: Boosting Concurrency of Shared Large Objects

an empty block, i.e., \( \text{val}(f) = \langle b_0 \rangle \) with \( \text{val}(b_0) = \varepsilon \). We say that \( f \) is valid and \( f \in F^\ell \) if \( \forall b_i \in \text{val}(f), b_i \in B^\ell \). Otherwise, \( f \) is invalid. Being a R/W object, one would expect that a fragmented object \( f \in F^\ell \), for any \( \ell \), supports the following operations:

- \( \text{read}(f) \) returns the list \( \langle \text{val}(b_0), \ldots, \text{val}(b_n) \rangle \), where \( \text{val}(f) = \langle b_0, b_1, \ldots, b_n \rangle \)
- \( \text{write}(D_0, \ldots, D_n)_f, |D_i| \leq \ell, \forall i \in [0, n] \), sets the value of \( f \) to \( \langle b_0, \ldots, b_n \rangle \) s.t. \( \text{val}(b_i) = D_i, \forall i \in [0, n] \).

Having the write operation to modify the values of all blocks in the list may hinder in many cases the concurrency of the object. For instance, consider the following execution \( \xi \). Let \( \text{val}(f) = \langle b_0, b_1 \rangle, \text{val}(b_0) = D_0, \text{val}(b_1) = D_1 \), and assume that \( \xi \) contains two concurrent writes by two different clients, one attempting to modify block \( b_0 \), and the other attempting to modify block \( b_1 \): \( \pi_1 = \text{write}(\langle D_0', D_1 \rangle)_f \) and \( \pi_2 = \text{write}(\langle D_0, D_1' \rangle)_f \), followed by a \( \text{read}(f) \). By linearizability, the read will return either the list written in \( \pi_1 \) or in \( \pi_2 \) on \( f \) (depending on how the operations are ordered by the linearizability property). However, as blocks are independent objects, it would be expected that both writes could take effect, with \( \pi_1 \) updating the value of \( b_0 \) and \( \pi_2 \) updating the value of \( b_1 \). To this respect, we redefine the write to only update one of the blocks of a fragmented object. Since the update does not manipulate the value of the whole object, which would include also new blocks to be written, it should allow the update of a block \( b \) with a value \( |D| > \ell \). This essentially leads to the generation of new blocks in the sequence. More formally, the update operation is defined as follows:

- \( \text{update}(b_i, D)_f \) updates the value of block \( b_i \in f \) such that:
  - if \( |D| \leq \ell \): sets \( \text{val}(b_i) = D \);
  - if \( |D| > \ell \): partition \( D = \{D_0, \ldots, D_k\} \) such that \( |D_j| \leq \ell, \forall j \in [0, k] \), set \( \text{val}(b_i) = D_0 \) and create blocks \( b'_j \), for \( j \in [1, k] \) with \( \text{val}(b'_j) = D_j \), so that \( f \) remains valid.

With the update operation in place, fragmented objects resemble store-collect objects presented in [3]. However, fragmented objects aim to minimize the communication overhead by exchanging individual blocks (in a consistent manner) instead of exchanging the list (view) of block values in each operation. Since the update operation only affects a block in the list of blocks of a fragmented object, it potentially allows for a higher degree of concurrency. It is still unclear what are the consistency guarantees we can provide when allowing concurrent updates on different blocks to take effect. Thus, we will consider that only operations read and update are issued in fragmented objects. Note that the list of blocks of a fragmented object cannot be reduced. The contents of a block can be deleted by invoking an update with an empty value.

Observe that as a fragmented object is composed of block objects, its operations are implemented by using read, write, and create block operations. The \( \text{read}(f) \) performs a sequence of read block operations (starting from block \( b_0 \) and traversing the list of blocks) to obtain and return the value of the fragmented object. Regarding update operations, if \( |D| \leq \ell \), then the \( \text{update}(b_i, D)_f \) operation performs a write operation on the block \( b_i \) as \( \text{write}(D)_b \). However, if \( |D| > \ell \), then \( D \) is partitioned into substrings \( D_0, \ldots, D_k \) each of length at most \( \ell \). The update operation modifies the value of \( b_i \) as \( \text{write}(D_0)_b \). Then, \( k \) new blocks \( b'_1, \ldots, b'_k \) are created as \( \text{create}(b'_j, D_j), \forall j \in [1, k] \), and are inserted in \( f \) between \( b_i \) and \( b_{i+1} \) (or appended at the end if \( i = |f| \)). The sequential specification of a fragmented object is defined as follows:
Definition 1 (Sequential Specification). The sequential specification of a fragmented object \( f \in \mathcal{F}^\ell \) over the complete sequential history \( H \) is defined as follows. Initially \( \text{val}(f) = \{b_0\} \) with \( \text{val}(b_0) = \varepsilon \). If at the invocation action of an operation \( \pi \) in \( H \) has \( \text{val}(f) = \{b_0, \ldots, b_n\} \) and \( \forall b_i \in f, \text{val}(b_i) = D_i \), and \( |D_i| \leq \ell \). Then:

- if \( \pi \) is a read\((f)_f \), then \( \pi \) returns \( \langle \text{val}(b_0), \ldots, \text{val}(b_n) \rangle \). At the response action of \( \pi \), it still holds that \( \text{val}(f) = \{b_0, \ldots, b_n\} \) and \( \forall b_i \in f, \text{val}(b_i) = D_i \).
- if \( \pi \) is an update\((b_i, D)_f \) operation, \( b_i \in f \), then at the response action of \( \pi \), \( \forall j \neq i, \text{val}(b_j) = D_j \), and
  - if \( |D| \leq \ell \): \( \text{val}(f) = \{b_0, \ldots, b_n\} \) and \( \text{val}(b_i) = D \);
  - if \( |D| > \ell \): \( \text{val}(f) = \{b_0, \ldots, b_i, b_{i+1}, \ldots, b_n\} \), such that \( \text{val}(b_i) = D^0 \) and \( \text{val}(b_{i}^j) = D^j \), \( \forall j \in [1, k] \), where \( D = D^0 | D^1 | \cdots | D^k \) and \( |D^j| \leq \ell \).

4 Fragmented Linearizability

A fragmented object is linearizable if it satisfies both the Liveness (termination) and Linearizability (atomicity) properties. A fragmented object implemented by a single linearizable block is trivially linearizable as well. Here, we focus on fragmented objects that may contain a list of multiple linearizable blocks, and consider only read and update operations. As defined, update operations are applied on single blocks, which allows multiple update operations to modify different blocks of the fragmented object concurrently. Termination holds since read and update operations on the fragmented object always complete. It remains to examine the consistency properties.

Linearizability: Let \( H_\xi \) be a sequential history of update and read invocations and responses on a fragmented object \( f \). Linearizability provides the illusion that the fragmented object is accessed sequentially respecting the real-time order, even when operations are invoked concurrently.

Definition 2 (Linearizability). A fragmented object \( f \) is linearizable if, given any complete history \( H \), there exists a permutation \( \sigma \) of all actions in \( H \) such that:

- \( \sigma \) is a sequential history and follows the sequential specification of \( f \), and
- for operations \( \pi_1, \pi_2 \), if \( \pi_1 \rightarrow \pi_2 \) in \( H \), then \( \pi_1 \) appears before \( \pi_2 \) in \( \sigma \).

Observe, that in order to satisfy Definition the operations must be totally ordered.

Let us consider again the sample execution \( \xi \) from Section 3. Since we decided not to use write operations, the execution changes as follows. Initially, \( \text{val}(f) = \{b_0, b_1\} \), \( \text{val}(b_0) = D_0 \), \( \text{val}(b_1) = D_1 \), and then \( \xi \) contains two concurrent update operations by two different clients, one attempting to modify the first block, and the other attempting to modify the second block: \( \pi_1 = \text{update}(b_0, D_0')_f \) and \( \pi_2 = \text{update}(b_1, D_1')_f \) \(|D_0'| \leq \ell \) and \( |D_1'| \leq \ell \), followed by a read\((f)_f \) operation. In this case, since both

---

5 The operator "\( | \cdot | \)" denotes concatenation. The exact way \( D \) is partitioned is left to the implementation.

6 Our formal definition of linearizability is adapted from [4].
Fig. 1: Executions showing the operations on a fragmented object. Fig. (a) shows linearizable reads on the fragmented object (and serialization points), and (b) reads on the fragmented object that are implemented with individual linearizable reads on blocks.

update operations operate on different blocks, independently of how \( \pi_1 \) and \( \pi_2 \) are ordered in the permutation \( \sigma \), the read \( f \) operation will return \( (D_0', D_1') \). Therefore, the use of these update operations has increased the concurrency in the fragmented object.

Using linearizable read operations on the entire fragmented object can ensure the linearizability of the fragmented object as can be seen in the example presented in Figure 1(a). However, providing a linearizable read when the object involves multiple R/W objects (i.e., an atomic snapshot) can be expensive or impact concurrency [9]. Thus, it is cheaper to take advantage of the atomic nature of the individual blocks and invoke one read operation per block in the fragmented object.

But, what is the consistency guarantee we can provide on the entire fragmented object in this case? As seen in the example of Fig. 1(b), two reads concurrent with two update operations may violate linearizability on the entire object. According to the real time ordering of the operations on the individual blocks, block linearizability is preserved if the first read on the fragmented object should return \( (D_0', D_1) \), while the second read returns \( (D_0, D_1') \). Note that we cannot find a permutation on these concurrent operations that follows the sequential specification of the fragmented object. Thus, the execution in Figure 1(b) violates linearizability. This leads to the definition of fragmented linearizability on the fragmented object, which relying on the fact that each individual block is linearizable, it allows executions like the one seen in Fig. 1(b). Essentially, fragmented linearizability captures the consistency one can obtain on a collection of linearizable objects, when these are accessed concurrently and individually, but under the "umbrella" of the collection.

In this respect, we specify each read \( f \) operation of a certain process, as a sequence of read \( b \) operations on each block \( b \in f \) by that process. In particular, a read operation read \( f \) that returns \( \langle \text{val}(b_0), \ldots, \text{val}(b_n) \rangle \) is specified by \( n + 1 \) individual read operations read \( f(b_0), \ldots, \text{read}(f(b_n)) \), that return \( \text{val}(b_0), \ldots, \text{val}(b_n) \), respectively, where read \( f(b_0) \rightarrow \ldots \rightarrow \text{read}(f(b_n)) \).

Then, given a history \( H \), we denote for an operation \( \pi \) the history \( H^\pi \) which contains the actions extracted from \( H \) and performed during \( \pi \) (including its invocation and response actions). Hence, if \( \text{val}(f) \) is the value returned by read \( f \), then \( H^{\text{read}(f)} \) contains an invocation and matching response for a read \( f \) operation, for each
\( b \in \text{val}(f) \). Then, from \( H \), we can construct a history \( H|_f \) that only contains operations on the whole fragmented object. In particular, \( H|_f \) is the same as \( H \) with the following changes: for each read\((\cdot)|_f \), if \( \langle \text{val}(b_0), \ldots, \text{val}(b_n) \rangle \) is the value returned by the read operation, then we replace the invocation of read\((\cdot)\) operation with the invocation of the read\((\cdot)|_b \) block with the response action for the read\((\cdot)|_f \) operation. Then we remove from \( H|_f \) all the actions in \( H|_{\text{read}(\cdot)} \).

**Definition 3 (Fragmented Linearizability).** Let \( f \in F^\ell \) be a fragmented object, \( H \) a complete history on \( f \), and \( \text{val}(f)|_H \subseteq B \) the value of \( f \) at the end of \( H \). Then, \( f \) is fragmented linearizable if there exists a permutation \( \sigma_b \) over all the actions on \( b \) in \( H \), \( \forall b \in \text{val}(f)|_H \), such that:

- \( \sigma_b \) is a sequential history that follows the sequential specification of \( b \),
- for operations \( \pi_1, \pi_2 \) that appear in \( H|_f \) extracted from \( H \), if \( \pi_1 \rightarrow \pi_2 \) in \( H|_f \), then all operations on \( b \) in \( H|_{\pi_1} \) appear before any operations on \( b \) in \( H|_{\pi_2} \) in \( \sigma_b \).

Fragmented linearizability guarantees that all concurrent operations on different blocks prevail, and only concurrent operations on the same blocks are conflicting. Consider two reads \( r_1 \) and \( r_2 \), s.t. \( r_1 \rightarrow r_2 \); then \( r_2 \) must return a supersequence of blocks with respect to the sequence returned by \( r_1 \), and that for each block belonging in both sequences, its value returned by \( r_2 \) is the same or newer than the one returned by \( r_1 \).

## 5 Implementing Files as Fragmented Coverable Objects

Having laid out the theoretical framework of Fragmented Objects, we now present a prototype implementation of a Distributed File System, we call CoBFS.

When manipulating files it is expected that a value update builds upon the current value of the object. In such cases a writer should be aware of the latest value of the object (i.e., by reading the object) before updating it. In order to maintain this property in our implementation we utilize coverable linearizable blocks as presented in [24]. Coverability extends linearizability with the additional guarantee that object writes succeed when associating the written value with the “current” version of the object. In a different case, a write operation becomes a read operation and returns the latest version and the associated value of the object. Due to space limitations we refer the reader to [24] for the exact coverability properties.

By utilizing coverable blocks, our file system provides fragmented coverability as a consistency guarantee. In our prototype implementation we consider each object to be a plain text file, however the underlying theoretical formulation allows for extending this implementation to support any kind of large objects.

**File as a coverable fragmented object:** Each file is modeled as a fragmented object with its blocks being coverable objects. The file is implemented as a linked-list of blocks with the first block being a special block \( b_0 \in B \), which we call the genesis block, and then each block having a pointer \( \text{ptr} \) to its next block, whereas the last block has a null pointer. Initially each file contains only the genesis block; the genesis block contains special purpose (meta) data. The \( \text{val}(b) \) of \( b \) is set as a tuple, \( \text{val}(b) = \langle \text{ptr}, \text{data} \rangle \).

---

\(^7\) The sequential specification of a block is similar to that of a R/W register [22], whose value has bounded length.
Overview of the Basic Architecture: The basic architecture of CoBFS appears in Fig. 2. CoBFS is composed of two main modules: (i) a Fragmentation Module (FM), and (ii) a Distributed Shared Memory Module (DSMM). In summary, the FM implements the fragmented object while the DSMM implements an interface to a shared memory service that allows read/write operations on individual block objects. Following this architecture, clients may access the file system through the FM, while the blocks of each file are maintained by servers through the DSMM. The FM uses the DSMM as an external service to write and read blocks to the shared memory. To this respect, CoBFS is flexible enough to utilize any underlying distributed shared object algorithm.

File and block id assignment: A key aspect of our implementation is the unique assignment of ids to both fragmented objects (i.e. files) and individual blocks. A file \( f \in F \) is assigned a pair \((cfid, cfseq) \in C \times \mathbb{N}\), where \( cfid \in C \) is the universally unique identifier of the client that created the file (i.e., the owner) and \( cfseq \in \mathbb{N} \) is the client’s local sequence number, incremented every time the client creates a new file and ensuring uniqueness of the objects created by the same client.

In turn, a block \( b \in B \) of a file is identified by a triplet \((fid, cid, cseq) \in F \times C \times \mathbb{N}\), where \( fid \in F \) is the identifier of the file in which the block belongs to, \( cid \in C \) is the identifier of the client that created the block (this is not necessarily the owner/creator of the file), and \( cseq \in \mathbb{N} \) is the client’s local sequence number of blocks that is incremented every time this client creates a block for this file (this ensures the uniqueness of the blocks created by the same client for the same file).

Distributed Shared Memory Module: The DSMM implements a distributed R/W shared memory based on an optimized coverable variant of the ABD algorithm, called CoABD [24]. The module exposes three operations for a block \( b \): dsmm-read\(_b\), dsmm-write\(_v\)_\(_b\), and dsmm-create\(_v\)_\(_b\). The specification of each operation is shown in Algorithm [1]. For each block \( b \), the DSMM maintains its latest known version \( ver_b \) and its associated value \( val_b \). Upon receipt of a read request for a block \( b \), the DSMM invokes a cvr-read operation on \( b \) and returns the value received from that operation.

To reduce the number of blocks transmitted per read, we apply a simple yet very effective optimization (Algorithm [2]): a read sends a READ request to all the servers in-
Lemma 1. The DSMM implements R/W coverable block objects.
Fig. 3: Example of a writer $x$ writing text at the beginning of the second block of a text file with id $f_{id} = 7$. The hash value of the existing second block “4bad..” is replaced with “d595..” and a new block with hash value “8223..” is inserted immediately after. The block $b_{id} = x_{7-2}$ and the new block $b_{id} = x_{7-4}$ are sent to the DSM.

**Proof.** When both the read and write operations perform two phases the correctness of the algorithm is derived from Theorem 10 in [24]. It is easy to see that the optimization does not violate linearizability. The second phase of a read is omitted when all the servers reply with a tag smaller or equal to the local tag of the reader $r$. Since however, a read propagates its local tag to a majority of servers at every tag update, then every subsequent operation will observe (and return) the latest value of the object to be associated with a tag at least as high as the local tag of $r$.

**Fragmentation Module:** The FM is the core concept of our implementation. Each client has a FM responsible for (i) fragmenting the file into blocks and identify modified blocks, and (ii) follow a specific strategy to store and retrieve the file blocks from the R/W shared memory. As we show later, the block update strategy followed by FM is necessary in order to preserve the structure of the fragmented object and sufficient to preserve the properties of fragmented coverability. For the file division of the blocks and the identification of the newly created blocks, the FM contains a **Block Identification (BI) module** that utilizes known approaches for data fragmentation and diff extraction.

**Block Identification (BI):** Given the data $D$ of a file $f$ the goal of BI is to break $D$ into data blocks $\langle D_0, \ldots, D_n \rangle$, s.t. the size of each $D_i$ is less than a predefined upper bound $\ell$. Furthermore, by drawing ideas from the RSYNC (Remote Sync) algorithm [26], given two versions of the same file, say $f$ and $f'$, the BI tries to identify blocks that (a) may exist in $f$ but not in $f'$ (and vice-versa), or (b) they have been changed from $f$ to $f'$. To achieve these goals BI proceeds in two steps: (1) it fragments $D$ into blocks, using the *rabin fingerprints* rolling hash algorithm [25], and (2) it compares the hashes of the blocks of the current and the previous version of the file using a string matching algorithm [5] to determine the modified/new data blocks. The role of BI within the architecture of CoBFS and its process flow appears in Fig. 5 while its specification is provided in Algorithm 3. A high-level description of BI has as follows:

- **Block Division:** Initially, the BI partitions a given file $f$ into data blocks based on its contents, using *rabin fingerprints*. This algorithm identifies the block boundaries
Algorithm 3 Fragmentation Module: BI and Operations on a file $f$ at client $p$

50: end function

and it performs content-based chunking by calculating and returning the fingerprints (block hashes) over a sliding window, and guarantees that each block identified has a bounded size of no more than $\ell$.

- **Block Matching:** Given the set of blocks $\langle D_0, \ldots, D_m \rangle$ and associated block hashes $\langle h_0, \ldots, h_m \rangle$ generated by the rabin fingerprint algorithm, the BI tries to match each hash to a block identifier, based on the block ids produced during the previous division of file $f$, say $\langle b_0, \ldots, b_n \rangle$. We produce the vector $\langle h(b_0), \ldots, h(b_n) \rangle$ where $h(b_i) = \text{hash}(\text{val}(b_i).data)$ from the current blocks of $f$, and using a string matching algorithm [5] we compare the two hash vectors to obtain one of the following statuses for each entry: (i) equal, (ii) modified, (iii) inserted, (iv) deleted.

- **Block Updates:** Based on the hash statuses computed through block matching previously, the blocks of the fragmented object are updated. In particular, in the case of equality, if $h_i = h(b_i)$ then $D_i$ is identified as the data of block $b_i$. In case of modification, e.g. $(h(b_i), h_i)$, an update($b_i, \langle D_i \rangle$) action is then issued to modify the data of $b_i$ to $D_i$ (Lines [19][13]). In case new hashes (e.g. $\langle h_i, h_k \rangle$) are inserted after the hash of block $b_j$ (i.e. $h(b_j)$), then the action update($b_j, \langle \text{val}(b_j).data, D_i, D_k \rangle$) is performed to create the new blocks after $b_j$ (Lines [15][19]). In our formulation block deletion is treated as a modification that sets an empty data value thus, in our implementation no blocks are deleted.
**FM Operations:** The FM’s external signature includes the two main operations of a fragmented object: read $f$, and update $f$. Their specifications appear in Algorithm [3]

Read operation - read($f, p$): To retrieve the value of a file $f$, a client $p$ may invoke a read($f, p$) to the fragmented object. Upon receiving, the FM issues a series of reads on file’s blocks; starting from the genesis block of $f$ and proceeding to the last block by following the pointers in the linked-list of blocks comprising the file. All the blocks are assembled into one file via the Assemble() function. The reader $p$ issues a read for all the blocks in the file. This is done to ensure the property stated in the following lemma:

Lemma 2. Let $\xi$ be an execution of CoBFS with two reads $\rho_1 = \text{read}_f(p)$ and $\rho_2 = \text{read}_f(q)$ from clients $p$ and $q$ on the fragmented object $f$, s.t. $\rho_1 \rightarrow \rho_2$. If $\rho_1$ returns a list of blocks $L_1$ and $\rho_2$ a list $L_2$, then $\forall b_i \in L_1$, then $b_i \in L_2$ and $\text{version}(b_i)_{L_1} \leq \text{version}(b_i)_{L_2}$.

Update operation - update($b, D$)$_f,p$: Here we expect that the update operation accepts a block id and a set of data blocks (instead of a single data object), since the division is performed by the BI module. Thus, $D = (D_0, \ldots, D_k)$, for $k \geq 0$, with the size $|D| = \sum_{i=0}^{k} |D_i|$ and the size of each $|D_i| \leq \ell$ for some maximum block size $\ell$. Client $p$ attempts to update the value of a block with identifier $b$ in file $f$ with the data in $D$. Depending on the size of $D$ the update operation will either perform a write on the block if $k = 0$, or it will create new blocks and update the block pointers in case $k > 0$.

Assuming that val$(b).ptr = b'$ then:

- $k = 0$: In this case update, for block $b$, calls write($\langle \text{val}(b).\text{ptr}, D_0, \langle p, \text{bseq} \rangle \rangle$)$_b$.
- $k > 0$: Given the sequence of chunks $D = (D_0, \ldots, D_k)$ the following block operations are performed in this particular order:
  
  $\rightarrow \text{create}(b_k = (f, p, bc_p++), \langle b', D_k \rangle, \langle p, 0 \rangle)$ **Block $b_k$ ptr points to $b'$**
  $\rightarrow \ldots$
  $\rightarrow \text{create}(b_1 = (f, p, bc_p++), \langle b_2, D_3 \rangle, \langle p, 0 \rangle)$ **Block $b_1$ ptr points to $b_2$**
  $\rightarrow \text{write}(\langle b_1, D_0 \rangle, \langle p, \text{bseq} \rangle)_b$ **Block $b$ ptr points to $b_1$**

The challenge here was to insert the list of blocks without causing any concurrent operation to return a divided fragmented object, while also avoiding blocking any ongoing operations. To achieve that, create operations are executed in a reverse order: we first create block $b_k$ pointing to $b'$, and we move backwards until creating $b_1$ pointing to block $b_2$. The last operation, write, tries to update the value of block $b_0$ with value $\langle b_1, D_0 \rangle$. If the last coverable write completes successfully, then all the blocks are inserted in $f$ and the update is successful; otherwise none of the blocks appears in $f$ and thus the update is unsuccessful. This is captured by the following lemma:

Lemma 3. In any execution $\xi$ of CoBFS, if $\xi$ contains an $\pi = \text{update}(b, D)_f,p$, then $\pi$ is successful iff the operation $b$.cbr-write called within $\text{dsmm-write}(\text{val}(b))_{b,p}$ is successful.

Proof. It is easy to see that if $\pi = \text{update}(b, D)_f,p$ is successful, then all the dsmm-write operations invoked within $\pi$, including $\text{dsmm-write}(\text{val}(b))_{b,p}$, are successful. It remains to show that $\pi$ can only be unsuccessful whenever $\text{dsmm-write}(\text{val}(b))_{b,p}$ is unsuccessful. In the case where $D$ contains a single chunk,
i.e. $D = \langle D_0 \rangle$ then $\pi$ invokes a single $dsmm\text{-write}(\text{val}(b))_{b,p}$ with $\text{val}(b)\.data = D_0$. If the $\text{cvr}\text{-write}$ invoked in that operation is unsuccessful then $\pi$ is also unsuccessful. In the case where $k > 0$, $\pi$ invokes $k - 1$ create operations with new block identifiers (due to the incremented block counter $bc$). The $\text{cvr}\text{-write}$ operation on every such block will be successful as (i) the block id $\langle f, p, bc \rangle$ (and thus the block) can only be generated by process $p$, and (ii) the block is not yet inserted in the link-list. So no other write operation will attempt to $\text{cvr}\text{-write}$ the same block concurrently. So the only operation that may fail in this case as well, is the $dsmm\text{-write}(\text{val}(b))_{b,p}$ as $b$ was a part of the list and may be accessed concurrently by a writer $q \neq p$.

Now a read operation may return a list that contains a block $b_i$ only if $b_i$ was written by a successful update operation. More formally:

**Lemma 4.** In any execution $\xi$ of $\text{CoBFS}$, if a $\rho = \text{read}_{f,p}$ operation returns a list $\mathcal{L}$ then for any block $b \in \mathcal{L}$ there exists successful $update(*)_{f,s}$ operation that either precedes or is concurrent to $\rho$ and invokes $sm\text{-create}(\text{val}(b))_{b}$ operation.

*Proof.* According to our protocol it is clear that a block with id $b$ appears in the list of $f$ only if that is created and written during an $update_{f,s}$ operation. Also, if the block is created by an update that precedes $\rho$, then no other block in the list will point to $b$, $\rho$ will not invoke a $sm\text{-read}$ operation for $b$, and thus $b \not\in \mathcal{L}$.

So it remains to examine the case where $\rho$ may obtain $b$ from an unsuccessful $update_{f,s}$. Let us assume by contradiction that a read operation may return a block $b$ for a file $f$ created by an unsuccessful update. Let $b \in \langle b_1, \ldots, b_n \rangle$, the list of blocks that the update needs to write on the DSM. In particular, the operation will create all the blocks $\langle b_2, \ldots, b_n \rangle$ and attempt to write block $b_1$. There are two cases to consider: (i) either $b$ is equal to $b_1$, or (ii) $b$ is in $\langle b_2, \ldots, b_n \rangle$.

If case (i) is true, then $\rho$ will invoke a $sm\text{-write}(\text{val}(b))_{b}$ as $b$ is the block that is updated. However, since we assume that the update was not successful, then by Lemma 3 the write operation is not successful. Thus, according to the coverable DSM, $b$ was never written and this contradicts the assumption that $\rho$ obtain $b \in \mathcal{L}$.

If case (ii) holds, then $b$ was created by $p$ (an operation that cannot fail). However, since the update is not successful, then $b_1$ was not written in the list. It is also true that there is no link path leading to $b$ since the only path was $b_1 \rightarrow b_2 \rightarrow \ldots \rightarrow b$. So, during the traversal of the blocks, the read operation will not see $b_1$ and thus will never reach and obtain $b$, contradicting again our initial assumption.

The above lemma will help us to show that the linked-list used for implementing our fragmented object stays connected in any execution.

**Lemma 5.** In any execution $\xi$ of $\text{CoBFS}$, if a $\text{read}_{f,p}$ operation returns a list $\mathcal{L} = \langle b_g, b_1, \ldots, b_n \rangle$ for a file $f$, then $\text{val}(b_g)\.ptr = b_1$, $\text{val}(b_i)\.ptr = b_{i+1}$, for $1 \leq i < n - 1$, and $\text{val}(b_n)\.ptr = \bot$.

*Proof.* Assume by contradiction that there exist some $b_i \in \mathcal{L}$, s.t. $\text{val}(b_i)\.ptr \neq b_{i+1}$ (or $\text{val}(b_g)\.ptr \neq b_1$). By Lemma 4, a block $b_i$ may appear in the list returned by a read operation only if it was created by a successful update operation, say w.l.o.g. $\pi = update(b,D)_{f,s}$. Let $D = \langle D_0, \ldots, D_k \rangle$ and $B = \langle b_1, \ldots, b_k \rangle$ be the set of $k - 1$
blocks created in $\pi$, with $b_i \in B$. By the design of the algorithm we create a single linked path from $b$ to $b_k$, by pointing $b$ to $b_1$ and each $b_j$ to $b_{j+1}$, for $1 \leq j < k$. Block $b_k$ points to the block pointed by $b$ at the invocation of $\pi$, say $b'$. So there exists a path $b \rightarrow b_1 \rightarrow \ldots \rightarrow b_i$ that also leads to $b_i$. According again to the algorithm, $b_{j+1} \in B$ is created and written before $b_j$, for $q \leq j < k$. So when the $b_j.cvR-write$ is invoked, the operation $b_{j+1}.cvR-write$ has completed, and thus when $b$ is written successfully all the blocks in the path are inserted successfully in $f$. So, if now $b_i$ is different than $b_k$ by the construction of the update then both $b_i$ and $b_{i+1}$ are in the list with $val(b_i).ptr = b_{i+1}$ contradicting our assumption.

If now $b_i = b_k$, then $val(b_i).ptr = b'$. Since $b$ was pointing to $b'$ at the invocation of $\pi$ then $b'$ was either (i) created during the update operation that also created $b$, or (ii) was created before $b$. In case (i), by Lemma 3, the update operation that created $b$ was successful and thus $b'$ must be created and inserted in $f$ as well. In case (ii) it follows that $b$ is the last inserted block of an update and is assigned to point to $b'$. With a simple induction one may show that the update operation that created $b'$ must precede the update that created $b$. Since no block is deleted, then $b'$ remains in $L$ when $b_i$ is created and thus $b_i$ points to an existing block. Furthermore, since $\pi$ was successful, then it successfully written $b$ and hence only the blocks in $B$ were inserted between $b$ and $b'$ at the response of $\pi$. So $b'$ must be the next block after $b_i$ in $L$ at the response of $\pi$ and there is a path between $b$ and $b'$. This completes our proof.

This leads us to the following:

**Theorem 1.** CoBFS implements a R/W Fragmented Coverable object.

**Proof.** By Lemma 1 every block operation in CoBFS satisfies coverability and together with Lemma 2 it follows that CoBFS implements a coverable fragmented object satisfying the properties presented in Definition 3. Also, the BI ensures that the size of each block is limited under a bound $\ell$ and Lemma 3 ensures that each operation obtains a connected list of blocks. Thus, CoBFS implements a valid fragmented object.

### 6 Preliminary Evaluation

To further appreciate the proposed approach from an applied point of view, we performed a preliminary evaluation of CoBFS against CoABD. Due to the design of the two algorithms, CoABD will transmit the entire file per read/update operation, while CoBFS will transmit as many blocks as necessary for an update operation, but perform as many reads as the number of blocks during a read operation. The two algorithms use the read optimization of Algorithm 2. Both were implemented and deployed on Emulab [27], a network testbed with tunable and controlled environmental parameters.

**Experimental Setup:** Across all experiments, three distinct types of distributed nodes are defined and deployed within the emulated network environment as listed below. Communication between the distributed nodes is via point-to-point bidirectional links implemented with a DropTail queue.

- **writer** $w \in W \subseteq C$: a client that dispatches update requests to servers.
reader $r \in R \subseteq C$: a client that dispatches read requests to servers

server $s \in S$: listens for reader and writer requests and is responsible for maintaining the object replicas according to the underlying protocol they implement.

**Performance Metrics:** We assess performance using: (i) *operational latency*, and (ii) the *update success ratio*. The operational latency is computed as the sum of communication and computation delays. In the case of COBFS, computational latency encompasses the time necessary for the FM to fragment a file object and generate the respective hashes for its blocks. The update success ratio is the percentage of update operations that have not been converted to reads (and thus successfully changed the value of the indented object). In the case of CoABD, we compute the percentage of successful updates on the file as a whole over the number of all updates. For COBFS, we compute the percentage of file updates, where all individual block updates succeed.

**Scenarios:** Both algorithms are evaluated under the following experimental scenarios:

- **Scalability:** examine performance as the number of service participants increases
- **File Size:** examine performance when using different initial file sizes
- **Block Size:** examine performance under different block sizes (COBFS only)

We use a *stochastic* invocation scheme in which reads are scheduled randomly from the intervals $[1...rInt]$ and updates from $[1...wInt]$, where $rInt,wInt = 4$ sec. To perform a fair comparison and to yield valuable observations, the results shown are compiled as averages over five samples per each scenario.

**Scalability Experiments:** We varied the number of readers $|R|$, the number of writers $|W|$, and the number of servers $|S|$ in the set $\{5, 10, 15, 20, 25, 30, 35, 40, 45, 50\}$. While testing for readers’ scalability, the number of writers and servers was kept constant, $|W|,|S| = 10$. Using the same approach, scalability of writers, and in turn of servers, was tested while preserving the two other types of nodes constant (i.e. $|R|,|S| = 10$ and $|R|,|W| = 10$ respectively). In total, each writer performed 20 updates and each reader 20 reads. The size of the initial file used was set to 18 kB, while the maximum, minimum and average block sizes (*rabin fingerprints* parameters) were set to 64 kB, 2 kB and 8 kB respectively.

**File Size Experiments:** We varied the $f_{size}$ from 1 MB to 1 GB by doubling the file size in each simulation run. The number of writers, readers and servers was fixed to 5. In total, each writer performed 5 updates and each reader 5 reads. The maximum, minimum and average block sizes were set to 1 MB, 512 kB and 512 kB respectively.

**Block Size Experiments:** We varied the minimum and average $b_{sizes}$ of COBFS from 1 kB to 64 kB. The number of writers, readers and servers was fixed to 10. In total, each writer performed 20 updates and each reader 20 reads. The size of the initial file used was set to 18 kB, while the maximum block size was set to 64 kB.

**Results:** Overall, our results suggest that the efficiency of COBFS is inversely proportional to the number of block operations, rather than the size of the file. This is primarily due to the individual block-processing nature of COBFS. More in detail:

**Scalability:** In Fig. 4(a), the operational latency of updates in COBFS remains almost unchanged and smaller than of CoABD. This is because CoABD writer updates a rather small file, while each COBFS writer updates a subset of blocks which are modified or created. The computational latency of FM in COBFS is negligible, when compared to the total update operation latency, because of the small file size. In Fig. 4(c), we
Fig. 4: Simulation results for algorithms CoABD and CoBFS.
observe that the update operation latency in CoABD increases even more as the number of servers increases. As more updates are successful in CoBFS, reads may transfer more data compared to reads in CoABD, explaining their slower completion as seen in Fig. 4(b). Also, readers send multiple read block requests of small sizes, waiting each time for a reply, while CoABD readers wait for a message containing a small file.

**Concurrency:** The percentage of successful file updates achieved by CoBFS are significantly higher than those of CoABD. This holds for both cases where the number of writers increased (see Fig. 4(a)) and the number of servers increased (see Fig. 4(c)). This demonstrates the boost of concurrency achieved by CoBFS. In Fig. 4(a) we notice that as the number of writers increases (hence, concurrency increases), CoABD suffers greater number of unsuccessful updates, i.e., updates that have become reads per the coverability property. Concurrency is also affected when the number of blocks increases, Fig. 4(d). The probability of two writes to collide on a single block decreases, and thus CoBFS eventually allows all the updates (100%) to succeed. CoABD does not experience any improvement as it always manipulates the file as a whole.

**File Size:** Figure 4(d) demonstrates that the update operation latency of CoBFS remains at extremely low levels. The main factor that significantly contributes to the slight increase of CoBFS update latency is the FM computation latency, Fig. 4(e). We have set the same parameters for the rabin fingerprints algorithm for all the initial file sizes, which may have favored some file sizes but burdened others. An optimization of the rabin algorithm or a use of a different algorithm for managing blocks could possibly lead to improved FM computation latency; this is a subject for future work. The CoBFS update communication latency remains almost stable, since it depends primarily on the number and size of update block operations. That is in contrast to the update latency exhibited in CoABD which appears to increase linearly with the file size. This was expected, since as the file size increases, it takes longer latency to update the whole file.

Despite the higher success rate of CoBFS, the read latency of the two algorithms is comparable due to the low number of update operations. The read latencies of the two algorithms with and without the read optimization can be seen in Fig. 4(f). The CoABD read latency increases sharply, even when using the optimized reads. This is in line with our initial hypothesis, as CoABD requires reads to request and propagate the whole file each time a newer version of the file is discovered. Similarly, when read optimization is not used in CoBFS, the latency is close of CoABD. Notice that each read that discovers a new version of the file needs to request and propagate the content of each individual block. On the contrary, read optimization decreases significantly the CoBFS read latency, as reads transmit only the contents of the blocks that have changed.

**Block Size:** From Figs. 4(g)(h) we can infer that when smaller blocks are used, the update and read latencies reach their highest values. In both cases, small $b_{size}$ results in the generation of larger number of blocks from the division of the initial file. Additionally, as seen in Fig. 4(g), the small $b_{size}$ leads to the generation of more new blocks during update operations, resulting in more update block operations, and hence higher latencies. As the minimum and average $b_{size}$ increase, lower number of blocks need to be added when an update is taking place. Unfortunately, smaller number of blocks leads to a lower success rate. Similarly, in Fig. 4(h), smaller block sizes require more read block operations to obtain the file’s value. As the minimum and average $b_{size}$
increase, lower number of blocks need to be read. Thus, further increase of the minimum and average $b_{sizes}$ forces the decrease of the latencies, reaching a plateau in both graphs. This means that the emulation finds optimal minimum and average $b_{sizes}$ and increasing them does not give better (or worse) latencies.

7 Conclusions

We have introduced the notion of linearizable and coverable fragmented objects and proposed an algorithm that implements coverable fragmented files. It is then used to build CoBFS, a prototype distributed file system in which each file is specified as a linked-list of coverable blocks. CoBFS adopts a modular architecture, separating the object fragmentation process from the shared memory service allowing to follow different fragmentation strategies and shared memory implementations. We showed that it preserves the validity of the fragmented object (file) and satisfies fragmented coverability. The deployment on Emulab serves as a proof of concept implementation. The evaluation demonstrates the potential of our approach in boosting the concurrency and improving the efficiency of R/W operations on strongly consistent large objects.

For future work, we aim to perform a comprehensive experimental evaluation of CoBFS that will go beyond simulations (e.g., full-scale, real-time, cloud-based experimental evaluations) and to further study parameters that may affect the performance of the operations (e.g., file size, block size, etc), as well as to build optimizations and extensions, in an effort to unlock the full potential of our approach.

A Fragmented Objects with Coverable Blocks

When writing a value to a linearizable R/W object, the value written does not need to be dependent on the previous written value. However, in some objects (e.g. files), it is expected that a value update will build upon (and thus avoid to overwrite) the current value of the object. In such cases a writer should be aware of the latest value of the object (i.e., by reading the object) before updating it. Although a read-modify-write (RMW) semantic would be more appropriate for this type of objects, it can only be achieved through consensus, which is known to be merely impossible to solve in an asynchronous environment with crashes [14].

To this respect, in [24] the notion of coverability was introduced to leverage the solvability of R/W object implementations, while providing a weak RMW object. Informally, coverability, extends linearizability with the additional guarantee that object writes succeed when associating the written value with the “current” version of the object. In a different case, a write operation becomes a read operation and returns the latest version and the associated value of the object.

More formally, coverability uses a totally ordered set of versions, say Versions, and introduces the notion of versioned (coverable) objects. A coverable object is a type of R/W object where each value written is assigned with a version from the set Versions. The coverable R/W object \( X \) offers two operations: (i) \( X.cvr-write(val, ver)_p \), and (ii) \( X.cvr-read()_p \). A process \( p \) invokes a \( cvr-write(val, ver)_p \) operation when it performs a write operation that attempts to change the value of the object. The operation returns the value of the object and its associated version, along with a flag informing whether the operation has successfully changed the value of the object or failed. A write is successful if it changes the value of the register; otherwise the write is unsuccessful. The read operation \( cvr-read()_p \) involves a request to retrieve the value of the object. The response of this operation is the value of the register together with the version of the object that this value is associated with. Denoting a successful write \( cvr-write(v, ver)(v, ver', chg)_p \) as \( tr-write(ver)[ver']_p \) (updating the object from version \( ver \) to \( ver' \)), and \( cvr-write(v, ver)(v', ver', unchg)_p \) as \( tr-write(ver)[ver', unchg]_p \), a coverable implementation satisfies the following properties (for the formal definition see [24]).

Definition 4 (Coverability [24]). A valid execution \( \xi \) is coverable with respect to a total order \( \prec_\xi \) on all successful write operations, \( W_{\xi, succ} \), in \( \xi \) if:

- (Consolidation) If a \( tr-write(ver_j)[*] \in W_{\xi, succ} \) then \( ver_j \) is larger than any version written by a preceding successful write operation.

- (Continuity) if \( tr-write(ver)[ver_i] \in W_{\xi, succ} \), then \( ver \) was written by a preceding write operation or \( ver = \perp \) the initial version

- (Evolution) The version of the object is incrementally evolving and thus for two version 'chains' formed by concurrent writes on a single initial version \( ver \), the last version of the longest chain is larger than the latest version on the shorter chain.
If a fragmented object utilizes coverable blocks, instead of linearizable blocks, then Definition 3 provides what we would call **fragmented coverability**: Concurrent update operations on different blocks would all prevail (as long as each update is tagged with the latest version of each block), whereas only one update operation on the same block would prevail (all the other updates on the same block that are concurrent with this would become a read operation). As we see in the next section fragmented coverability is a good alternative to RMW semantics to implement large objects, like files, of which any new value may depend on the current value of the object.

**B Additional Operations Supported by the Prototype**

To enhance the practicality of our prototype we have equipped it with additional operations, which are all framed around the two main operations of the FM.

Besides updating the contents of a file, reading a file and managing blocks, the FM supports a number of other useful operations, such as creating a file, renaming a file, deleting a file, obtaining a list of the existing files and an advanced list operation.

To store information about the files that the FM manages, internally the FM maintains a dictionary $D$. In more detail, a key entry is a file path $f_{path}$ of $f_{id}$, and the corresponding value is a tuple consisting the $b_{id}$ of the genesis block $b_{g}$ of $f_{id}$ and the file id $f_{id}$ of the fragmented file $f$. That is, $D : \{key, value\} = \{f_{path}, \langle b_{g}, f_{id} \rangle \}$.

The FM uses $f_{path}$ as key for this dictionary, in order to be able to monitor the changes that take place for each file. However, in the level of the Atomic Shared Object Algorithm, all the information about a file is stored based on its $f_{id}$.

It is worth mentioning that, the format of a block that sending to the Atomic Shared Object Algorithm, is a dictionary containing the header and the literal data of the block. The header includes some information about the block, i.e. the hash value, a boolean value that indicates if the block is the genesis one, the next $b_{id}$, the block size and the modification time of the block. If the block is the genesis block, the header it also contains the $f_{path}$.

- **Create Operation**: When a new file is created on the client’s filesystem, the FM fragments it into its respective blocks (including the genesis block), and writes them on the servers by invoking a sequence of write operations for the entirety of the blocks comprising the file.

- **Rename Operation**: When a file is renamed on the client, the FM executes a special write request, where it writes the genesis block of the file that includes the new $f_{path}$ in its header.

- **Delete Operation**: When a file is deleted on the client, the FM discards the $f_{id}$ entry from its dictionary and sends a special write request to the servers, with the genesis bid $b_{gen}$ of the file. The servers set the tag of the $b_{gen}$ to -1, in order to notify that the file is deleted in case another client tries to have access to it before the delete operation is completed. As a result, no further operations can be performed on the deleted file, since the FM and the servers do not have access to its genesis block.
- **List Operation**: To obtain the list of existing files, the FM contacts the servers and obtains the $f_{id}$, the $f_{path}$ and the genesis block id $b_{id}$ of each file, which then allows for further read operations to be issued.

- **Advanced List Operation**: The advanced list operation, is similar to the simple list one, giving some additional information about each file. At first, the FM requests a simple list operation. Then for each file in the resulted list, it requests a series of block list operations. Each block list operation informs the FM about the size and the modified size of the block. As a result, the FM can calculate the size of the whole file and the maximum modified time that a block of the file has changed.
