Abstract. Verifying quantum systems has attracted a lot of interest in the last decades. In this paper, we study the quantitative model-checking of quantum continuous-time Markov chains (quantum CTMCs). The branching-time properties of quantum CTMCs are specified by continuous stochastic logic (CSL), which is famous for verifying real-time systems, including classical CTMCs. The core of checking the CSL formulas lies in tackling multiphase until formulas. We develop an algebraic method using proper projection, matrix exponentiation, and definite integration to symbolically calculate the probability measures of path formulas. Thus the decidability of CSL is established. To be efficient, numerical methods are incorporated to guarantee that the time complexity is polynomial in the encoding size of the input model and linear in the size of the input formula. A running example of Apollonian networks is further provided to demonstrate our method.

1. Introduction

Rapid development has taken place on quantum hardware in recent years [ZWD+20, CDG21]. In the meantime, quantum software will be crucial in implementing quantum algorithms and harnessing the power of quantum computers, e.g. Shor’s algorithm with an exponential speed-up for integer factorization [Sho94] and Grover’s algorithm with a quadratic speed-up for unstructured search [Gro96]. The first practical quantum programming language QCL appeared in Ömer’s work [Ome98]. The quantum guarded command language (qGCL) was presented to program a “universal” quantum computer [SZ00]. Selinger [Sel04] proposed functional programming languages QFC with high-level features. To ensure reliability, all

Key words and phrases: model checking, quantitative reasoning, formal logic, quantum computing.
kinds of verification techniques [DP06, YF21] need to be developed for various quantum algorithms and protocols.

Model-checking [CGP99, BK08] is one of the most successful technologies for verifying classical hardware and software systems. There are also many explorations on applying model-checking to discrete-time quantum systems [YF21], such as quantum programs and quantum (discrete-time) Markov chains. However, it is also worth studying continuous-time models in quantum computing. In this paper, we consider a novel model of quantum continuous-time Markov chain (quantum CTMC). It is a composite system consisting of a classical subsystem and a quantum subsystem. In a classical CTMC, the instantaneous descriptions (IDs) are given by probability distributions over a finite set $S$ of classical states. Whereas, in a quantum CTMC, the IDs are given by positive semi-definite matrices, which bear quantum information, distributed over those classical states $S$. The ID’s evolution of a particular class of quantum CTMCs that have only one classical state is a closed system in which there are no other classical states (its environment) to interact with. In comparison, the ID’s evolution of a quantum CTMC with more than one classical state is an open system. Let us imagine a swinging pendulum in a mechanical clock. In an ideal situation, the pendulum does not suffer any unwanted interaction, such as air friction, from its environment, which is a closed system. In practice, however, air friction indeed exists, which would eventually make the pendulum cease. As interactions happen between the pendulum and its environment, it is an open system. It is evident that open systems are more common in the real world, which motivates us to study the open system — quantum CTMC. The dynamical system of quantum CTMC can be characterized by the Lindblad master equation:

$$\frac{d\rho(t)}{dt} = \mathcal{L}(\rho(t)) \quad (1.1)$$

where $\rho(t)$ is the ID of the system at time $t$, and $\mathcal{L}$ is a linear function of $\rho(t)$ (to be described in Subsection 2.2).

Under the model of quantum CTMC, we can develop the cylinder set of paths with a computable probability measure, which is obtained by proper projection on the ID $\rho$ in Eq. (1.1) for ruling out dissatisfying paths and matrix exponentiation of the linear function $\mathcal{L}$ for computing the probability distribution as time goes by. Thereby we establish the probability space to do the formal quantitative reasoning. As a kind of real-time system, the branching-time properties are popularly specified by continuous stochastic logic (CSL). The core of checking the CSL formulas lies in tackling the multiphase until formula. It requires the temporal property that any satisfying path should meet a sequence of state constraints in turn, and requires the timing constraint that the switch time-stamps should be in some appointed time intervals. Specifically, the switch time-stamps are in the absolute timing that are measured from the start. It guides us to design a nested definite integral concerning the time variables interpreted as the switch time-stamps to collect the measure of the candidate paths phase by phase. By the mathematical tools of projection, matrix exponentiation and definite integration, we can decide the CSL formula with time complexity being polynomial in the encoding size of the input quantum CTMC and linear in the size of the input CSL formula, besides the complexity of the query — how sufficiently the Euler constant $e$ should be approached. For the consideration of practical efficiency, we also incorporate numerical methods — the scaling and squaring method for matrix exponentiation and the Riemann sum for definite integration — to yield a polynomial-time procedure for the satisfaction probability. Furthermore, we provide a running example of Apollonian
networks to demonstrate our method, and show the usefulness of our method via checking the percolation performance of those networks.

1.1. Related Work.

Checking on CTMC. The IDs for a continuous-time Markov chain (CTMC) are represented by probability distributions. Aziz et al. [ASSB96] initiated the model-checking on CTMC in 1996. They introduced the continuous stochastic logic (CSL) to specify temporal properties of the CTMC. Roughly speaking, the syntax of CSL amounts to that of computation tree logic (CTL) plus the multiphase until formula $\Phi_0 U^{z_0} \Phi_1 U^{z_1} \Phi_2 \cdots U^{z_{K-1}} \Phi_K$ and the probability quantifier formula $\Pr_{z}(\cdot)$ defined on those IDs. They proved the decidability of CSL by number-theoretic analysis. An approximate model-checking algorithm for a reduced version of CSL was provided by Baier et al. [BKH99], in which multiphase until formulas are restricted to binary until formulas $\Phi_1 U \Phi_2$. Under this logic, they applied the efficient numerical technique — uniformization — for transient analysis [BHHK00]. The approximate algorithms have been extended for multiphase until formulas using stratification [ZJNH11, ZJNH12]. After that, Xu et al. considered the multiphase until formulas over the CTMC equipped with a cost/reward structure [XZJ+16]. An algebraic algorithm was proposed to attack this problem, whose effectiveness is ensured by number-theoretic results and algebraic manipulation. Most of the above algorithms have been implemented in probabilistic model checkers, like PRISM [KNP11], Storm [DJKV17] and EPMC [FHL+22]. However, the IDs of the quantum CTMC are represented by positive semi-definite matrices, which generalize the diagonal matrices encoded for probability distributions. It leads to the fact that quantum CTMCs generalize classical CTMCs, so new formalism must be developed for this situation, as done in the current paper.

Checking on quantum DTMC. A quantum discrete-time Markov chain (quantum DTMC) is a composite model on classical state space (a finite set) and quantum state space (a continuum), on which the evolution is discrete-time given by quantum operations [LF15]. Gay et al. [GNP08] restricted the quantum operations to Clifford group gates (i.e., Hadamard, Pauli, CNOT and the phase gates) and the whole state space as a finite set of describable states, named stabilizer states, that are closed under those Clifford group gates. They applied the model checker PRISM to verify the protocols of quantum superdense coding, quantum teleportation, and quantum error correction. Whereas, Feng et al. proposed Markov chain with transitions given by the general quantum operations [FYY13]. Under the model, the authors considered the reachability probability [YFY13], the repeated reachability probability [PHTY17], and the model-checking of a quantum analogy of CTL [FY13]. A key step in their work is decomposing the whole state space (known as a Hilbert space) into a direct-sum of some bottom strongly connected component (BSCC) subspaces plus a maximal transient subspace concerning a given quantum operation describing the evolution of the quantum DTMC [YFY13, GFY18]. After the decomposition, all the above problems were shown to be computable/decidable in polynomial time concerning the dimension of the Hilbert space. In contrast to the quantum operations in discrete-time evolution, when considering quantum CTMC, the general linear operators should be admitted to describe the rates of state transitions in continuous time. For this purpose, we will characterize the continuous-time evolution by the Lindblad master equation in the present work.
Linear-time logic vs branching-time logic. All of the above literature are concerned with branching-time logic that classifies all paths into satisfying ones and dissatisfying ones, and compares the measure of satisfying paths with a predefined threshold. Fewer works concerning linear-time logics impose constraints on the measure of all paths at some critical time periods. Guan and Yu introduced continuous linear logic (CLL) over CTMCs [GY22], and proved the decidability by real root isolation of exponential polynomials. Xu et al. initiated the model-checking on quantum CTMCs, in which the decidability of signal temporal logic (STL) was established, again, by real root isolation [XMGY21]. Both CLL and STL are linear-time logics. However, checking the more popular branching-time logic over quantum CTMCs, as far as we know, remains open.

Contribution. The contributions of the present paper can be summarised as:
(1) We consider the novel model of quantum CTMC that has a more precise description of a composite system — consisting of a classical subsystem and a quantum subsystem — than the existing work [XMGY21].
(2) We prove the decidability of CSL over quantum CTMCs and give a numerical approach in polynomial time to compute the probability measure.
(3) A running example of Apollonian networks is provided to show the utility of our method.

Organization. The rest of this paper is organized as follows. Section 2 recalls some notions and notations from quantum computing and number theory. In Section 3 we introduce the model of quantum CTMC, and establish the probability space. Based on that, we will check the CSL formula for specifying branching-time properties over quantum CTMCs in Section 4. We further prove the decidability of CSL and give an efficient numerical approach. Section 5 is the conclusion. The implementation is delivered in Appendix A.

2. Preliminaries

2.1. Quantum Computing. Here we recall some basic notions and notations from quantum computing [NC00], which will be widely used in this paper. Let \( \mathcal{H} \) be a Hilbert space with finite dimension \( d \), that is, a vector space over complex numbers \( \mathbb{C} \) equipped with an inner product. We employ the Dirac notations as follows:
\[
\begin{align*}
\langle \psi \rangle & \text{ is a unit column vector labelled with } \psi; \\
\langle \psi \rangle & := \langle \psi \rangle^\dagger \text{ is the Hermitian adjoint (transpose and entry-wise complex conjugate) of } \langle \psi \rangle; \\
\langle \psi_1 | \psi_2 \rangle & := \langle \psi_1 | \psi_2 \rangle \text{ is the inner product of } | \psi_1 \rangle \text{ and } | \psi_2 \rangle; \\
| \psi_1 \rangle \langle \psi_2 | & := | \psi_1 \rangle \otimes | \psi_2 \rangle \text{ is the outer product where } \otimes \text{ denotes tensor product;} \\
| \psi_1, \psi_2 \rangle & := | \psi_1 \rangle \otimes | \psi_2 \rangle \text{ is a shorthand of the tensor product } | \psi_1 \rangle \otimes | \psi_2 \rangle.
\end{align*}
\]
Fixing an orthonormal basis \( \{| \psi_i \rangle : 1 \leq i \leq d \} \) of \( \mathcal{H} \), \( | \psi \rangle \in \mathcal{H} \) can be linearly expressed as \( \sum_{i=1}^{d} c_i | \psi_i \rangle \) with \( c_i \in \mathbb{C} \) and \( \sum_{i=1}^{d} |c_i|^2 = 1 \). This \( | \psi \rangle \) is called a superposition if it has two or more nonzero terms \( c_i | \psi_i \rangle \) under that basis. For example, the familiar elements \( | \pm \rangle := (| 0 \rangle \pm | 1 \rangle) / \sqrt{2} \) are superpositions over the basis \( \{| 0 \rangle, | 1 \rangle \} \).
Linear operator. We will mainly consider the linear operators on $\mathcal{H}$. Here such a parameter $\mathcal{H}$ can be omitted when it is clear from the context. A linear operator $\gamma$ is Hermitian if $\gamma = \gamma^\dagger$; it is positive if $\langle \psi | \gamma | \psi \rangle \geq 0$ holds for all $|\psi\rangle \in \mathcal{H}$. A projector $P$ is a positive operator of the form $\sum_{i=1}^d |\psi_i\rangle\langle\psi_i|$ for some orthonormal elements $|\psi_i\rangle \in \mathcal{H}$ ($1 \leq i \leq d$). Clearly, there is a bijective map between projectors $P = \sum_{i=1}^k |\psi_i\rangle\langle\psi_i|$ and subspaces of $\mathcal{H}$ that are spanned by $\{|\psi_i\rangle : 1 \leq i \leq k\}$. In summary, positive operators are Hermitian operators whose eigenvalues are all nonnegative; projectors are positive operators, all of whose nonzero eigenvalues are 1. The identity operator $I$ is the linear operator $\sum_{i=1}^d |\psi_i\rangle\langle\psi_i|$ for some orthonormal basis $\{|\psi_i\rangle : 1 \leq i \leq d\}$ of $\mathcal{H}$. A linear operator $U$ is unitary if $UU^\dagger = U^\dagger U = I$. The trace of a linear operator $\gamma$ is defined as $\text{tr}(\gamma) := \sum_{i=1}^d \langle \psi_i | \gamma | \psi_i \rangle$ for some orthonormal basis $\{|\psi_i\rangle : 1 \leq i \leq d\}$ of $\mathcal{H}$. It is worth noting that the trace function is actually independent of the orthonormal basis selected. For a linear operator $\gamma_{A,B}$ on the composite Hilbert space $\mathcal{H}_A \otimes \mathcal{H}_B$, we can define the partial traces as:

$$\text{tr}_A(\gamma_{A,B}) := \sum_{i=1}^{d_A} (|\psi_i^A\rangle \otimes I_B)\gamma_{A,B}(|\psi_i^A\rangle \otimes I_B)$$

and

$$\text{tr}_B(\gamma_{A,B}) := \sum_{i=1}^{d_B} (I_A \otimes |\psi_i^B\rangle\langle\psi_i^B|)\gamma_{A,B}(I_A \otimes |\psi_i^B\rangle\langle\psi_i^B|),$$

where $I_A$ (resp. $I_B$) is the identity operator on $\mathcal{H}_A$ (resp. $\mathcal{H}_B$), $d_A$ (resp. $d_B$) is the dimension of $\mathcal{H}_A$ (resp. $\mathcal{H}_B$), and $\{|\psi_i^A\rangle : 1 \leq i \leq d_A\}$ (resp. $\{|\psi_i^B\rangle : 1 \leq i \leq d_B\}$) is some orthonormal basis of $\mathcal{H}_A$ (resp. $\mathcal{H}_B$).

Quantum state. The quantum states are given by the form of probabilistic ensembles $\{(p_i, |\psi_i\rangle) : 1 \leq i \leq k\}$ with $p_i > 0$ and $\sum_{i=1}^k p_i = 1$. An alternative representation is using positive operators $\rho = \sum_{i=1}^k p_i |\psi_i\rangle\langle\psi_i|$, named density operators, whose traces are unit as $\text{tr}(\rho) = \sum_{i=1}^k p_i \text{tr}(\rho |\psi_i\rangle\langle\psi_i|) = 1$. Here those $|\psi_i\rangle$ are not necessarily orthonormal. To be more explicit, we resort to the spectral decomposition [NC00, Box 2.2] that $\rho = \sum_{i=1}^d \lambda_i |\lambda_i\rangle\langle\lambda_i|$, where $|\lambda_i\rangle$ are eigenvectors interpreted as the eigenstates of $\rho$ and $\lambda_i$ are eigenvalues interpreted as the probabilities of taking the eigenstates $|\lambda_i\rangle$. It is worth noting that the spectral decomposition of $\rho$ is not unique, but the number of nonzero eigenvalues counted with multiplicities is unique since it is exactly the rank of $\rho$. When there is only one eigenstate with positive probability, $\rho$ is said to be a pure state; otherwise it is a mixed state. In other words, a pure state $|\psi\rangle\langle\psi|$ (or simply $|\psi\rangle$) indicates the system state which we completely know; a mixed state $\sum_{i=1}^d \lambda_i |\lambda_i\rangle\langle\lambda_i|$ gives all possible system states $|\lambda_i\rangle$ with a total probability of $\sum_{i=1}^d \lambda_i = 1$. We denote by $\mathcal{D}$ the set of density operators, and by $\mathcal{D}^{\leq 1}$ the set of partial density operators that are positive operators with trace bounded by 1. Sometimes, we need to extract local information from a composite system. It can be achieved by the partial traces mentioned in Eq. (2.1), which result in the reduced density operators $\rho_A = \text{tr}_B(\rho_{A,B})$ on $\mathcal{H}_A$ and $\rho_B = \text{tr}_A(\rho_{A,B})$ on $\mathcal{H}_B$, respectively. For example, considering the Bell state $\rho_{A,B} = \frac{1}{2}(|0,0\rangle\langle0,0| + |1,1\rangle\langle1,1|)$, we can get the reduced density operators $\rho_A = \text{tr}_B(\rho_{A,B}) = \frac{1}{2}(|0\rangle\langle0| + |1\rangle\langle1|)$ and $\rho_B = \text{tr}_A(\rho_{A,B}) = \frac{1}{2}(|0\rangle\langle0| + |1\rangle\langle1|)$. In other words, the mixed states $\rho_A$ on $\mathcal{H}_A$ and $\rho_B$ on $\mathcal{H}_B$ are traced from the pure state $\rho_{A,B}$ on $\mathcal{H}_A \otimes \mathcal{H}_B$. 
Quantum operation. The quantum operations (also known as super-operators) are completely positive operators that map from the set \( \mathcal{D} \) of density operators to itself. As a special case, all unitary transformations \( \{ U \} \) are quantum operations that act on pure states as \( |\psi\rangle \mapsto U|\psi\rangle \) and on mixed states as \( \rho \mapsto U\rho U^\dagger \). Generally speaking, every quantum operation can be written in Kraus representation \( \{ \mathbf{E}_j : 1 \leq j \leq m \} \) for some \( m \in \mathbb{N} \), where \( \mathbf{E}_j \) are Kraus operators satisfying \( \sum_{j=1}^m \mathbf{E}_j^\dagger \mathbf{E}_j = \mathbb{I} \), so that it acts on quantum states as \( \rho \mapsto \sum_{j=1}^m \mathbf{E}_j \rho \mathbf{E}_j^\dagger \). Here, the condition \( \sum_{j=1}^m \mathbf{E}_j^\dagger \mathbf{E}_j = \mathbb{I} \) is the so-called *trace-preservation*, due to

\[
\text{tr} \left( \sum_{j=1}^m \mathbf{E}_j \rho \mathbf{E}_j^\dagger \right) = \sum_{j=1}^m \text{tr}(\mathbf{E}_j \rho \mathbf{E}_j^\dagger) = \sum_{j=1}^m \text{tr}(\mathbf{E}_j^\dagger \mathbf{E}_j \rho) = \text{tr} \left( \sum_{j=1}^m \mathbf{E}_j^\dagger \mathbf{E}_j \rho \right) = \text{tr}(\rho). \tag{2.2}
\]

It is worth noting that the Kraus representation of a quantum operation is not unique, but the number \( m \) of Kraus operators can be bounded by \( d^2 \). It follows from the facts that quantum operations are linear operators on \( \mathcal{D} \), and that \( \mathcal{D} \) is contained in the set of Hermitian operators which is a linear space of dimension \( d^2 \).

State evolution. A closed system is an ideal system that does not suffer from any unwanted interaction from outside environment. State evolution in a closed system is induced by some unitary transformation \( |\psi(t + \Delta t)\rangle = U(\Delta t)|\psi(t)\rangle \), where \( |\psi(t)\rangle \) is the state of the system at time \( t \). From the identity \( U(\Delta t) = \exp(-iH\Delta t) \), we could determine the Hamiltonian (a Hermitian operator) \( H \) in the Schrödinger equation characterizing that state evolution:

\[
\frac{d |\psi(t)\rangle}{dt} = -iH |\psi(t)\rangle. \tag{2.3}
\]

An open system interacts with its environment. Composed with the environment, the large system is closed. In more detail, for a mixed state \( \rho = \sum_{i=1}^k \tilde{p}_i |\psi_i\rangle \langle \psi_i| \) in an open system, there is a pure state in the large system

\[
\hat{\rho} = \left( \sum_{i=1}^k \sqrt{\tilde{p}_i} |\psi_i, \text{env}_i\rangle \right) \left( \sum_{i=1}^k \sqrt{\tilde{p}_i} \langle \psi_i, \text{env}_i| \right)
\]

for some orthonormal states \( |\text{env}_i\rangle \) of the environment. After the purification, state evolution in the large system is induced by the unitary transformation \( \hat{\rho}(t + \Delta t) = \hat{U}(\Delta t)\hat{\rho}(t)\hat{U}^\dagger(\Delta t) \) as above. By tracing out the environment, we get the quantum operation in the original system:

\[
\rho(t + \Delta t) = \sum_{i=1}^k (I \otimes |\text{env}_i\rangle \langle \text{env}_i|)\hat{\rho}(t + \Delta t)(I \otimes |\text{env}_i\rangle) = \sum_j \mathbf{E}_j(\Delta t)\rho(t)\mathbf{E}_j^\dagger(\Delta t),
\]

where the last equation comes from Kraus representation of the current quantum operation. Based on those Kraus operators \( \mathbf{E}_j \), we will obtain the Lindblad master equation that characterizes the state evolution of the open system in the coming subsection.
2.2. Lindblad Master Equation. The quantum continuous-time Markov chain considered in this paper is a kind of open systems induced by the quantum operation

\[ \rho(t + \Delta t) = \sum_{j=0}^{m} E_j \rho(t) E_j^\dagger. \]  

The Lindblad master equation [Lin76, GKS76] could be obtained by knowing the structure of those operators \( E_j \). The dynamical system like other Markov models has the memoryless property, i.e., its state evolution is determined only by the current state. It requires that \( E_j \) should depend only on the infinitesimal time \( \Delta t \), not on the time \( t \). So it suffices to expand \( E_j \) into power series, particularly determining the coefficients of \((\Delta t)^0 = 1, (\Delta t)^{1/2} = \sqrt{\Delta t}, (\Delta t)^1 = \Delta t\), and so on if necessary.

First, by \( \lim_{\Delta t \to 0} \rho(t + \Delta t) = \rho(t) \), we can see that i) there exists an operator, saying \( E_0(\Delta t) \), that amounts to \( I \cdot 1 + o(1) \), where \( o((\Delta t)^k) \) means \( \lim_{\Delta t \to 0} o((\Delta t)^k)/(\Delta t)^k = 0 \) for \( k \geq 0 \), and ii) other operators \( E_j(\Delta t) \) \((j > 0) \) amount to \( o(1) \).

Next, supposing \( E_j(\Delta t) = L_j \sqrt{\Delta t} + o(\sqrt{\Delta t}) \) \((j > 0) \), we get

\[ \sum_{j=1}^{m} E_j(\Delta t) \rho(t) E_j^\dagger(\Delta t) = \sum_{j=1}^{m} L_j \rho(t) L_j^\dagger \Delta t + o(\Delta t). \]  

But the quantum operation \( \{L_j : 1 \leq j \leq m\} \) is not trace-preserving. To resolve it, \( E_0(\Delta t) \) is further supposed to be \( I - iH \Delta t - \frac{1}{2} \sum_{j=1}^{m} L_j^\dagger L_j \Delta t + o(\Delta t) \) where \( H \) is Hermitian, so that

\[ E_0(\Delta t) \rho(t) E_0^\dagger(\Delta t) = \rho(t) + \left[ -iH \rho(t) + i\rho(t)H - \frac{1}{2} \sum_{j=1}^{m} (L_j^\dagger L_j \rho(t) + \rho(t)L_j^\dagger L_j) \right] \Delta t + o(\Delta t), \]  

while the quantum operation \( \{I - iH \Delta t - \frac{1}{2} \sum_{j=1}^{m} L_j^\dagger L_j \Delta t\} \cup \{L_j : 1 \leq j \leq m\} \) is trace-preserving and \( \sum_{j=0}^{m} E_j^\dagger(\Delta t) E_j(\Delta t) = I + o(\Delta t) \).

Finally, putting Eqs. (2.4), (2.5) and (2.6) into

\[ \rho' = \lim_{\Delta t \to 0} \frac{\rho(t + \Delta t) - \rho(t)}{\Delta t}, \]

we obtain the Lindblad master equation for characterizing the quantum continuous-time Markov chain. It is of the following form

\[ \rho' = -i[H, \rho] + i\rho H + \sum_{j=1}^{m} \left( L_j \rho L_j^\dagger - \frac{1}{2} L_j^\dagger L_j \rho - \frac{1}{2} \rho L_j^\dagger L_j \right) \]

\[ = -i[H, \rho] + \sum_{j=1}^{m} \left( L_j \rho L_j^\dagger - \frac{1}{2} \{L_j^\dagger L_j, \rho\} \right), \]

where \([A, B] := AB - BA\) denotes the commutator between two linear operators \( A \) and \( B \), and \( \{A, B\} := AB + BA \) denotes the anti-commutator. The term \(-i[H, \rho]\) describes the evolution of the internal system; the term \( L_j \rho L_j^\dagger - \frac{1}{2} \{L_j^\dagger L_j, \rho\} \) represents the interaction between the system and its environment. In other words, to characterize the evolution of an open system, it is necessary to use those linear operators \( L_j \) besides the Hermitian one \( H \).
For the given quantum operation (2.4), those linear operators $L_j (j > 0)$ are determined by $E_j$ and the Hermitian operator $H$ is determined by $E_0$. Conversely, once we are given the operators $L_j (j > 0)$ and $H$, the quantum operation (2.4) are also determined. It entails that the Lindblad master equation is the most general type of Markovian and time-homogeneous master equation describing (generally non-unitary) state evolution that preserves the laws of quantum mechanics, i.e., complete positivity and trace-preservation.

We now turn to derive the solution of Eq. (2.7). Two useful functions are defined as:

- $L_2V(\gamma) := \sum_{i=1}^d \sum_{j=1}^d \langle i | \gamma | j \rangle | i, j \rangle$ that rearranges entries of the linear operator $\gamma$ on the Hilbert space $\mathcal{H}$ with dimension $d$ as a column vector; and
- $V_2L(v) := \sum_{i=1}^d \sum_{j=1}^d \langle i, j | v | i \rangle | j \rangle$ that rearranges entries of the column vector $v$ as a linear operator.

Here, $L_2V$ and $V_2L$ are pronounced “linear operator to vector” and “vector to linear operator”, respectively. They are mutually inverse functions, so that if a linear operator (resp. its vectorization) is determined, its vectorization (resp. the original linear operator) is determined. Hence, we can freely choose one of the two representations for convenience. For any linear operators $A, B, C$, their product $D = ABC$ has the transformation

$$L_2V(D) = (A \otimes C^T)L_2V(B),$$

where $T$ denotes transpose. Then, we can reformulate Eq. (2.7) as the linear ordinary differential equation

$$L_2V(\rho') = M \cdot L_2V(\rho),$$

where $M = -iH \otimes I + iI \otimes H^T + \sum_{j=1}^m (L_j \otimes L_j^\dagger - \frac{1}{2}L_j^\dagger L_j \otimes I - \frac{1}{2}I \otimes L_j^T L_j^\dagger)$ is the governing matrix with * denoting entry-wise complex conjugate. As a result, we get the desired solution $L_2V(\rho(t)) = \exp(M \cdot t) \cdot L_2V(\rho(0))$ or equivalently $\rho(t) = V_2L(\exp(M \cdot t) \cdot L_2V(\rho(0)))$ in a closed form. It is obtained in polynomial time by the standard method [Kai80].

2.3. Number Theory. We will show the decidability of a temporal logic, which is based on the following essential facts in number theory.

**Definition 2.1.** A number $\alpha$ is algebraic, denoted $\alpha \in \mathbb{A}$, if there is a nonzero $\mathbb{Q}$-polynomial $f_\alpha(z)$, satisfying $f_\alpha(\alpha) = 0$; otherwise $\alpha$ is transcendental.

In the above definition, such a polynomial $f_\alpha(z)$ is called the minimal polynomial of $\alpha$ if it is irreducible. The degree $D$ of $\alpha$ is $\deg_z(f_\alpha)$. A popular encoding of $\alpha$ [Coh93, Subsection 4.2.1] is using the minimal polynomial $f_\alpha$ plus an isolation disk in the complex plane that distinguishes $\alpha$ from other roots of $f_\alpha$. So the encoding size $||\alpha||$ is the number of bits used to store the minimal polynomial and the isolation disk.

**Definition 2.2.** Let $\mu_1, \ldots, \mu_m$ be irrational complex numbers. Then the field extension $\mathbb{Q}(\mu_1, \ldots, \mu_m) : \mathbb{Q}$ is the smallest set that contains $\mu_1, \ldots, \mu_m$ and is closed under arithmetic operations, i.e. addition, subtraction, multiplication and division.

Here those irrational complex numbers $\mu_1, \ldots, \mu_m$ are called the generators of the field extension. A field extension is simple if it has only one generator. For instance, the field extension $\mathbb{Q}(\sqrt{2}) : \mathbb{Q}$ is exactly the set $\{a + b\sqrt{2} : a, b \in \mathbb{Q}\}$.

**Lemma 2.3** [Loo83, Algorithm 2]. Let $\alpha_1$ and $\alpha_2$ be two algebraic numbers of degrees $D_1$ and $D_2$, respectively. There is an algebraic number $\mu$ of degree at most $D_1D_2$, such that the field extension $\mathbb{Q}(\mu) : \mathbb{Q}$ is exactly $\mathbb{Q}(\alpha_1, \alpha_2) : \mathbb{Q}$. 
For a collection of algebraic numbers $\alpha_1, \ldots, \alpha_m$ appearing in the input instance, by repeatedly applying Lemma 2.3, we can obtain a simple field extension $\mathbb{Q}(\mu) : \mathbb{Q}$ that can generate all $\alpha_1, \ldots, \alpha_m$.

**Lemma 2.4** [Coh93, Corollary 4.1.5]. Let $\alpha$ be an algebraic number of degree $D$, and $g(z)$ a polynomial with and degree $Dg$ and coefficients taken from $\mathbb{Q}(\alpha) : \mathbb{Q}$. There is a $\mathbb{Q}$-polynomial $f(z)$ of degree at most $DDg$, such that roots of $g(z)$ are those of $f(z)$.

The above lemma entails that roots of any polynomial with coefficients taken from algebraic numbers ($\lambda$-polynomial for short) are also algebraic.

**Theorem 2.5** (Lindemann 1882) [Bak75, Theorem 1.4]. For any nonzero algebraic numbers $\alpha_1, \ldots, \alpha_m$ and any distinct algebraic numbers $\lambda_1, \ldots, \lambda_m$, the sum $\sum_{i=1}^{m} \alpha_i e^{\lambda_i}$ with $m \geq 1$ is nonzero.

Hence the sign of a given real number with the form $\sum_{i=1}^{m} \alpha_i e^{\lambda_i}$ is decidable, which can be achieved by sufficiently approximating the Euler constant $e$. But the complexity of the procedure is unknown as studied in the existing literature [COW16, HLXL18]. It becomes a query (also known as oracle) in our work.

### 3. Quantum Continuous-Time Markov Chain

In this section, we first introduce the model of quantum continuous-time Markov chain, which subsumes the classical continuous-time Markov chain. Based on that, we will establish a probability space over paths to reason about real-time properties. An algebraic approach using matrix exponentiation is presented to calculate those measurable events in the probability space.

**Definition 3.1.** Let $AP$ be a set of atomic propositions throughout this paper. A labelled quantum continuous-time Markov chain (quantum CTMC for short) $\Omega$ over the Hilbert space $\mathcal{H}$ is a triple $(S, Q, L)$, in which

- $S$ is a finite set of classical states;
- $Q$ is the transition generator function given by two parts of information:
  - a Hermitian operator $H$ with the form $\sum_{s \in S} |s\rangle \langle s| \otimes H_s$, where $H_s$ are Hermitian operators on $\mathcal{H}$,
  - a finite set of linear operators $L_j$ with the form $|s_j,2\rangle \langle s_j,1| \otimes L_{s_j,1,s_j,2}$ for some $s_j,1, s_j,2 \in S$, $(s_j,1 \neq s_j,2)$, where $L_{s_j,1,s_j,2}$ are linear operators on $\mathcal{H}$; and
- $L : S \rightarrow 2^{AP}$ is a labelling function.

To distinguish the dynamic states $\rho(t)$ of $\Omega$ in time $t$ from other static (classical or quantum) states, we call $\rho(t)$ by instantaneous descriptions (IDs). Usually, a density operator of the form $\rho(0) = \sum_{s \in S} |s\rangle \langle s| \otimes \rho_s$ is appointed as the initial ID of $\Omega$, where $\rho_s \in \mathcal{D}_{\mathcal{H}}^{\leq 1}$ satisfy $\sum_{s \in S} \text{tr}(\rho_s) = 1$.

Every classical state $s \in S$ can be quantized by a pure state $|s\rangle$, satisfying that all of them are orthogonal pairwise. Specifically, if the system is in a classical state $s$, it could be thought of being in the quantum state $|s\rangle$ with unit probability mass. Further, the superpositions, saying $c_1 |s_1\rangle + c_2 |s_2\rangle$, could be quantized states between the basis states $|s_1\rangle$ and $|s_2\rangle$ with probability mass $|c_1|^2$ and $|c_2|^2$ respectively. Let $\mathcal{C} := \text{span} \{ |s\rangle : s \in S \}$ be the Hilbert space corresponding to the classical system, and $\mathcal{H}_{\text{eq}} := \mathcal{C} \otimes \mathcal{H}$ the enlarged Hilbert space corresponding to the whole classical–quantum system. The dimension of $\mathcal{H}_{\text{eq}}$
is \( N := nd \) where \( n = |S| \) and \( d = \text{dim}(\mathcal{H}) \). This parameter \( N \) is used to reflect the size of the quantum CTMC \( \Omega \).

The IDs \( \rho \) for a quantum CTMC \( \Omega \) are represented by density operators on the enlarged Hilbert space \( \mathcal{H}_{eq} \) with the mixed structure \( \sum_{s \in S} |s\rangle \langle s| \otimes \rho_s \) where \( \rho_s \in \mathcal{D}_{\mathcal{H}}^\leq 1 \) are partial density operators, satisfying \( \sum_{s \in S} \text{tr}(\rho_s) = 1 \). Such a mixed structure entails that the entries \( (|s_1\rangle \otimes \mathbf{I})\rho(|s_2\rangle \otimes \mathbf{I}) \) are zero whenever \( s_1 \neq s_2 \). It underlies the key difference between the classical state space \( C \) and the quantum state space \( \mathcal{H} \) that:

- The classical state space \( C \) has finitely many basis states \( |s\rangle \) with \( s \in S \), which are known and fixed a priori. After tracing out the quantum state space \( \mathcal{H} \), the reduced density operator on \( C \) is a probability distribution over these classical states, and cannot be a superposition.
- The quantum state system \( \mathcal{H} \) has uncountably many pure states \( |\psi\rangle \), due to the postulate of quantum mechanics [NC00] that the space of pure states is a continuum. Those pure states \( |\psi\rangle \) are superpositions on the orthonormal basis of \( \mathcal{H} \), which is neither known nor fixed a priori. It will bring extra technical hardness to verifying quantum models.

We can also regard these IDs \( \rho \) as positive-operator valued distributions over classical states \( S \), which generalize probability distributions representing the IDs of a classical CTMC. Under the mixed structure, the current model of quantum CTMC is more precise than the one proposed in [XMGY21] that does not clarify the difference between the classical state space and the quantum state space.

The transition generator function \( Q \) is functionally similar to the transition rate matrix in the classical CTMC, but employs the Lindblad master equation to characterize the continuous-time transition. It gives rise to a universal way to describe the behavior of a quantum CTMC that keeps the ID \( \rho \) in the mixed structure \( \sum_{s \in S} |s\rangle \langle s| \otimes \rho_s \), following from the generality of the Lindblad master equation. In more detail, we can see:

- Each \( H_s \) determines the internal evolution at classical state \( s \), i.e., \( -i[H_s, \rho_s] \) is one term of \( \rho'_s \), and \( H = \sum_{s \in S} |s\rangle \langle s| \otimes H_s \) gives all such individual internal evolution by \( -i[H, \rho] \).
- Whereas, \( L_j = |s_{j,2}\rangle \langle s_{j,1}| \otimes L_{s_{j,1},s_{j,2}} \) determines the external evolution from classical state \( s_1 \) to \( s_2 \), i.e., \( L_j \rho L_j^\dagger - \frac{1}{2} \{L_j, \rho \} \) is one term of \( \rho' \).

It is notable that, as required in Eq. (2.7), \( H_s \) can be chosen as arbitrary Hermitian operators and \( L_{s_{j,1},s_{j,2}} \) can be arbitrary linear operators, which makes the model much expressive. A state \( s \) is absorbing if all transitions from it are removed, which is achieved by some projectors to be defined later.

Recall that a classical CTMC \( \mathcal{C} \) is a triple \( (S, Q, L) \), where \( S \) and \( L \) are the same as the components in the quantum CTMC \( \Omega = (S, Q, L) \), and \( Q : (S \times S) \rightarrow \mathbb{R}_{\geq 0} \) is the transition rate matrix, i.e., \( Q[s_1, s_2] \) gives the transition rate from state \( s_1 \) to \( s_2 \). In fact, the model of quantum CTMC \( \Omega = (S, Q, L) \) extends that of classical CTMC \( \mathcal{C} = (S, Q, L) \), so the model of quantum CTMC is more expressive. It can be seen from the following lemma:

**Lemma 3.2** [XMGY21, Lemma 10]. Given a CTMC \( \mathcal{C} \), it can be modelled by a quantum CTMC \( \Omega \) over one-dimensional Hilbert space \( \mathcal{H} \).

For the sake of computability, the entries of \( \rho_s \), \( H_s \) and \( L_{s_{j,1},s_{j,2}} \) in the model of quantum CTMC are supposed to be algebraic numbers in the simple field extension \( \mathbb{Q}(\mu) : \mathbb{Q} \) for some algebraic number \( \mu \). The encoding size \( \|\mu\| \) is used to reflect the encoding size of operands in \( \Omega \). Together with the dimension \( N \) of \( \mathcal{H}_{eq} \), they are two key parameters in the encoding size \( \|\Omega\| \), which will be used to analyze the complexity of our method afterward.
Example 3.3. Here we will study the open quantum walk (OQW) along Apollonian networks (ANs) [AHAdS05]. ANs have small-world and scale-free properties. Small-world property means that there is a relatively short path between two nodes despite the often large size of networks, and scale-free property implies that most of the nodes in the network are connected to only a few nodes while few nodes are connected to a large number of nodes. With the two properties, ANs provide an excellent facility to analyze dynamical processes taking place on networked systems, including percolation and electrical conduction. In the meanwhile, ANs serve as a valuable tool for studying properties of various walk models, including (discrete- and continuous-time) random walks and quantum walks [XLL08].

ANs are generated in such a way: At the initial generation, the network consists of three nodes marked as 0, 1 and 2, respectively. At each subsequent generation, a new node is added inside each triangle and linked to the three vertices of that triangle, as shown in Figure 1.

Consider a qutrit, a quantum state in a 3-dimensional Hilbert space, is walking along the first generation of AN [PGMS15], which is depicted in Figure 1b. As the qutrit may interact with its environment, some noise from the network channel will affect the walking of the qutrit which can be described by linear operators, say, $A = |x⟩⟨x|$, $B = |y⟩⟨y|$ and $C = |z⟩⟨z|$, where $|x⟩ = (1, 1, 1)^T/\sqrt{3}$, $|y⟩ = (1, w, w^2)^T/\sqrt{3}$ and $|z⟩ = (1, w^2, w)^T/\sqrt{3}$ with $w = \exp(2\pi i/3)$. The OQW can be modelled by the quantum CTMC $Q = (S, Q, L)$ over the Hilbert space $H = \text{span} \{ |0⟩, |1⟩, |2⟩ \}$, where $S = \{ 0, 1, 2, 3 \}$ represents the four nodes; Node 3 has a label “center” and other nodes have none; the transition function $Q$ is given by the Hermitian operator $H = 0$ and the following 12 linear operators:

\[
\begin{align*}
L_1 &= |1⟩⟨0| \otimes A \\
L_2 &= |2⟩⟨0| \otimes B \\
L_3 &= |3⟩⟨0| \otimes C \\
L_4 &= |2⟩⟨1| \otimes A \\
L_5 &= |0⟩⟨1| \otimes B \\
L_6 &= |3⟩⟨1| \otimes C \\
L_7 &= |0⟩⟨2| \otimes A \\
L_8 &= |1⟩⟨2| \otimes B \\
L_9 &= |3⟩⟨2| \otimes C \\
L_{10} &= |0⟩⟨3| \otimes C/\sqrt{3} \\
L_{11} &= |1⟩⟨3| \otimes (B + C/\sqrt{3}) \\
L_{12} &= |2⟩⟨3| \otimes (A + C/\sqrt{3}).
\end{align*}
\]

An initial ID $\rho(0)$ could be, saying $|3⟩⟨3| \otimes \frac{1}{\sqrt{3}} I$. Here, the left operand $|3⟩⟨3|$ in the tensor product means that we are definitely in Node 3 in the classical system, the right operand $\frac{1}{\sqrt{3}} I$ means that we are in one of three basis states $|0⟩$ through $|2⟩$ with equal probability $\frac{1}{3}$ in the quantum system, and they together determine the ID in the whole classical–quantum system. 

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure1.png}
\caption{The first three generations of ANs}
\end{figure}
A path $\omega$ of a quantum CTMC $\Omega$ is an infinite sequence $s_0 \xrightarrow{\tau_0} s_1 \xrightarrow{\tau_1} s_2 \xrightarrow{\tau_2} \cdots$. It means that $\omega$ starts at $s_0$, and sojourns there up to time $t_0 = \tau_0$ (but excluding $\tau_0$); then $\omega$ jumps to $s_1$ at time $t_0$, and sojourns there up to time $t_1 = \tau_0 + \tau_1$; then $\omega$ jumps to $s_2$ at time $t_1$, and sojourns there up to time $t_2 = t_1 + \tau_2$; and so on. The times $\tau_k$ ($k \geq 0$) are called sojourn times that are measured from the instants when the prior transitions $s_{k-1} \rightarrow s_k$ take place; while the times $t_k$ ($k \geq 0$) are switch time-stamps that are measured from the start of the path. A finite path $\hat{\omega}$ is a finite fragment of such a path $\omega$, e.g.

\[
\begin{align*}
&\omega_0 \xrightarrow{\tau_0} \omega_1 \xrightarrow{\tau_1} \omega_2 \xrightarrow{\tau_2} \cdots \xrightarrow{\tau_{K-1}} \omega_K, \\
&\text{Namely, the state } \omega(t) \text{ of } \omega \text{ at time } t \text{ is } s_k \text{ for } t \in [t_{k-1}, t_k),
\end{align*}
\]

where $t_{-1}$ is defined to be zero for convenience. Let Path be the set of paths of $\Omega$.

To formally reason about quantitative properties of quantum CTMC, we will establish the probability space over paths as follows:

**Definition 3.4.** A measurable space is a pair $(\Omega, \Sigma)$, where $\Omega$ is a nonempty set and $\Sigma$ is a $\sigma$-algebra on $\Omega$ that is a collection of subsets of $\Omega$, satisfying:

- $\Omega \in \Sigma$, and
- $\Sigma$ is closed under countable union and complement.

In addition, a probability space is a triple $(\Omega, \Sigma, \Pr)$, where $(\Omega, \Sigma)$ is a measurable space and $\Pr : \Sigma \rightarrow [0, 1]$ is a probability measure, satisfying:

- $\Pr(\Omega) = 1$,
- $\Pr(A) \geq 0$ for any $A \in \Sigma$, and
- $\Pr(\bigcup_i A_i) = \sum_i \Pr(A_i)$ for any pairwise disjoint $A_i \in \Sigma$.

Note that any finite path $\hat{\omega} = s_0 \xrightarrow{\tau_0} s_1 \xrightarrow{\tau_1} s_2 \xrightarrow{\tau_2} \cdots \xrightarrow{\tau_{K-1}} s_K$ is of measure zero, since it requires that the transitions from $s_{k-1}$ to $s_k$ ($k > 0$) take place instantaneously. It cannot collect any positive probability from a countable union of such events. To fix it, we use the cylinder set of paths, which is defined as

\[
\text{Cyl}(s_0 \xrightarrow{J_0} s_1 \xrightarrow{J_1} s_2 \xrightarrow{J_2} \cdots \xrightarrow{J_{K-1}} s_K) := \\
\left\{ \omega \in \text{Path}: \omega = s_0 \xrightarrow{\tau_0} s_1 \xrightarrow{\tau_1} s_2 \xrightarrow{\tau_2} \cdots \xrightarrow{\tau_{K-1}} s_K, \ \tau_k \in J_k \right\}.
\]

Here, these time intervals $J_k$ ($0 \leq k < K$) are relatively timing, as they are measured from the instants when the prior transitions $s_{k-1} \rightarrow s_k$ take place. Let $\Omega = \text{Path}$, and $\Pi \subseteq 2^\Omega$ be countably many cylinder sets Cyl of paths plus the empty set $\emptyset$. By [BK08, Chapter 10], there is a smallest $\sigma$-algebra $\Sigma$ of $\Pi$ that contains $\Pi$ and is closed under countable union and complement. The pair $(\Omega, \Sigma)$ forms a measurable space.

Next, for a cylinder set $\text{Cyl} = s_0 \xrightarrow{J_0} s_1 \xrightarrow{J_1} s_2 \xrightarrow{J_2} \cdots \xrightarrow{J_{K-1}} s_K$, we define the probability measure along Cyl as $\Pr(\text{Cyl}) = \text{tr}(\rho^{(K)})$, where $\rho^{(K)}$ is the partial density operator in the $K$th phase. It can be calculated inductively by

\[
\begin{align*}
\rho^{(0)} &= P_{s_0} \cdot \rho(0) \\
\rho^{(k)} &= P_{s_k} \cdot \text{V2L}(\text{exp}(M_{s_{k-1}} | J_{k-1}) \cdot L2V(P_{s_{k-1}} \cdot \text{V2L}(\text{exp}(M_{s_{k-1}} \inf J_{k-1}) \cdot L2V(\rho^{(k-1)})))) \quad \text{if } k > 0,
\end{align*}
\]

where $|J_{k-1}| = \sup J_{k-1} - \inf J_{k-1}$ is the length of $J_{k-1}$, and $M_s$ is the governing matrix adapted for the transition generator function $Q_s$ consisting of the Hermitian operator $H \cdot P_s$ and finitely many linear operators $L_j P_s$. It is preferable to calculate those matrix
multiplication in Eq. (3.2) with right associativity, according to the forward semantics. Specifically, \( P_{s_{k-1}} \cdot \rho \) extracts the term \( |s_{k-1}\rangle \langle s_{k-1}| \otimes \rho_{s_{k-1}} \) from the ID \( \rho = \sum_{s \in S} |s\rangle \langle s| \otimes \rho_s \); \( \exp(M_{s_{k-1}}) \) gives rise to the state transition function, which carries the density operator of state \( s_{k-1} \) to all states \( s (s \in S) \) for some sojourn time \( \tau \) and preserves the density operator of state \( s (s \neq s_{k-1}) \). Totally, the induction is computing the final partial density operator \( \rho^{(k)} \) from \( \rho^{(k-1)} \), satisfying a sojourn at \( s_{k-1} \) for some time \( \tau_{k-1} \in J_{k-1} \). Similar to Vardi’s work for classical Markov chains [Var85], the domain of \( \Pr \) can be extended to \( \Sigma \), i.e., \( \Pr: \Sigma \to [0,1] \), which is well-defined under the countable union \( \bigcup_i A_i \) for any \( A_i \in \Sigma \) and the complement \( A^c \) for any \( A \in \Sigma \). Hence the triple \((\Omega, \Sigma, \Pr)\) forms a probability space.

**Example 3.5.** Let us continue to consider Example 3.3. The cylinder set \( Cyl_1 = 3 \xrightarrow{(0,1)} \)
\( 1 \xrightarrow{(1,2)} 3 \) contains all paths that take the transitions from Node 3 to Node 1 and then back to Node 3 with sojourn time in the intervals \( J_1 = (0,1) \) and \( J_2 = (1,2) \) respectively. We will compute its probability with the initial ID \( \rho(0) = |3\rangle \langle 3| \otimes |0\rangle \langle 0| \). Firstly, we have the projectors \( P_i = |i\rangle \langle i| \otimes I \) for \( i = 0, 1, 2, 3 \) and the corresponding adapted governing matrices

\[
\mathcal{M}_i = \sum_{j=1}^{12} [(L_j P_i) \otimes (L_j P_i)^\dagger - \frac{1}{2} (L_j P_i)^\dagger (L_j P_i) \otimes I - \frac{1}{2} I \otimes (L_j P_i)^\dagger (L_j P_i)^\dagger].
\]

Then, we inductively calculate the partial density operator in the \( k \)th phase:

\[
\begin{align*}
\rho^{(0)} &= P_3 \cdot \rho(0) = |3\rangle \langle 3| \otimes |0\rangle \langle 0|, \\
\rho^{(1)} &= P_1 \cdot V2L(\exp(M_3|J_1|)) \cdot L2V(P_3 \cdot V2L(\exp(M_3 \inf J_1) \cdot L2V(\rho^{(0)})))) = |1\rangle \langle 1| \otimes \rho_1, \\
\rho^{(2)} &= P_3 \cdot V2L(\exp(M_1|J_2|)) \cdot L2V(P_1 \cdot V2L(\exp(M_1 \inf J_2) \cdot L2V(\rho^{(1)})))) = |3\rangle \langle 3| \otimes \rho_3,
\end{align*}
\]

in which \( \rho_1 \) and \( \rho_3 \) are computable partial density operators on \( \mathcal{H} \) with the following numerical approximations obtained by the scaling and squaring method embedded with Padé approximations [ML03, AMH09] for matrix exponentials. That is, \( \exp(\mathcal{M}) = (\exp(\mathcal{M}/m))^m \) and \( \exp(\mathcal{M}/m) \approx P_k \) for some \( k, m \), where \( P_k \) is the \( k \)th Padé approximation to be described in Eq. (3.4),

\[
\begin{align*}
\rho_1 &\approx 0.184318 |0\rangle \langle 0| + (-0.092159 - 0.037415i)|0\rangle \langle 1| + |2\rangle \langle 0| + \langle 0| 0\rangle + 0.037415 |1\rangle \langle 1| + |2\rangle \langle 0| + 0.053744 |1\rangle \langle 1| + |2\rangle \langle 0| + 0.037415 |2\rangle \langle 1| + 0.053744 |2\rangle \langle 2|,
\rho_3 &\approx 0.016333 |0\rangle \langle 0| + (-0.008166 + 0.014145i)|0\rangle \langle 1| + |2\rangle \langle 0| + 0.016333 |1\rangle \langle 1| + |2\rangle \langle 0| + (-0.008166 + 0.014145i)|2\rangle \langle 1| + 0.016333 |2\rangle \langle 2|.
\end{align*}
\]

Finally we get the probability \( \Pr(Cyl_1) = \text{tr}(\rho^{(2)}) = \text{tr}(\rho_3) \approx 0.048999 \).

**Complexity.** By Eq. (3.2), the procedure of exactly calculating the probability \( \Pr(Cyl) \) requires \( K \) times of induction phases, for each of which the matrix exponentiation \( \exp(\mathcal{M}) \) dominates the computational cost. The matrix exponential \( \exp(\mathcal{M}) \) can be computed by Jordan decomposition as follows. Since \( \mathcal{M} \) is a matrix of dimension \( N^2 \) with entries being algebraic numbers taken from the simple field extension \( \mathbb{Q}(\mu) : \mathbb{Q} \), the characteristic polynomial \( g(x) \) of \( \mathcal{M} \) is an \( \mathbb{A} \)-polynomial with degree \( N^2 \), which can be obtained in \( O((N^2)^4) = O(N^8) \).
by [BPR06, Algorithm 8.17]. To further determine the eigenvalues of \( M \), we first convert \( g(x) \) to a \( \mathbb{Q} \)-polynomial \( f(x) \). It is achieved by Sylvester resultant [BPR06, Notation 4.12] — that is a determinant of dimension \( 2 \deg(\mu) \) — to eliminate the common occurrence of \( \mu \) in \( g(x) \) and \( f_\mu \) (the minimal polynomial of \( \mu \)). It results in the desired \( \mathbb{Q} \)-polynomial \( f(x) \) with degree at most \( D := N^2 \deg(\mu) \) has all roots of \( g(x) \). The variable elimination is in \( \mathcal{O}(D^3) \) by the standard determinant computation. The roots of \( f(x) \), including the eigenvalues of \( M \), can be determined in \( \mathcal{O}(D^5 \log(D)^2) \) by [BPR06, Algorithm 10.4]. So we get the Jordan decomposition \( M = T \cdot J \cdot T^{-1} \) in \( \mathcal{O}((N^2)^3) = \mathcal{O}(N^6) \) by computing the eigenvectors with respect to the known eigenvalues, where \( J \) is the Jordan canonical form of \( M \) and \( T \) is the transformation matrix. The same complexity holds for computing \( \exp(M\tau) = T \cdot \exp(J\tau) \cdot T^{-1} \). Hence the exactly calculating procedure is in

\[
\mathcal{O}(K \cdot D^5 \log(D)^2)
\]

that is bounded polynomially in the encoding size \( \| \Omega \| \) and linearly in the length \( K = |Cyl| \).

However, if we want to specify the complexity in terms of the number of qubits used in the Hilbert space \( \mathcal{H} \) of dimension \( d \), the complexity would turn out to be exponential in \( \log d \) as \( D = N^2 \deg(\mu) \) and \( N = nd \).

The above method aims to calculate the probability \( \Pr(Cyl) \) exactly, so that the decidability result could be established on later, i.e. deciding \( \Pr(Cyl) \sim c \) for some appointed probability threshold \( c \in [0, 1] \), where \( \sim \in \{=, <, >\} \) is a comparison operator. However, if we focus on the numerical value of \( \Pr(Cyl) \), an approximating method, saying the following one, suffices, which is potentially more efficient. Here, we have to address the problem that the uniformization method [BHKK00] is not directly applicable to compute \( \exp(M) \), since the governing matrix \( M \) has no structure of the generator matrix in a classical CTMC that is discretized as a Poisson process.

**Numerical speed-up.** To improve efficiency, we employ the state-of-the-art scaling and squaring method [ML03, AMH09] for the general matrix exponentiation. The technique is reliable, as it gives some warnings whenever it introduces excessive errors. The rationale and steps are described as follows.

1. We first *scale* \( \exp(M) \) by choosing \( m \) to be a power of two, satisfying \( \| \exp(M/m) \| \leq 1 \) where \( \| \cdot \| \) denotes Frobenius norm. Obviously, such a number \( m \) exists, which can further be chosen to be linear in the size \( N^4 \) of \( M \), i.e. \( m \in \mathcal{O}(N^4) \).

2. As a subroutine, we proceed to approximate \( \exp(M/m) \) reliably. The Padé approximation provides such a subroutine if \( \| \exp(M/m) \| \) is small, which is what have been done in the first step. The \( k \)th Padé approximation \( P_k \) is the fraction

\[
\left( \sum_{i=0}^{k} \frac{(2k-i)! \cdot k! \cdot (M/m)^i}{(2k)! \cdot (k-i)! \cdot i!} \right) / \left( \sum_{i=0}^{k} \frac{(2k-i)! \cdot k! \cdot (-M/m)^i}{(2k)! \cdot (k-i)! \cdot i!} \right),
\]

and its computational cost lies in \( k \) times of matrix multiplication, for each of which is in \( \mathcal{O}((N^2)^3) = \mathcal{O}(N^6) \). The subroutine terminates whenever the difference \( \| P_{k+1} - P_k \| \) of two successive approximations \( P_k \) and \( P_{k+1} \) is less than a predefined tolerance \( \epsilon \). As the sequence \( \{P_k\}_{k \in \mathbb{N}} \) is exponentially convergent to \( \exp(M/m) \), i.e., the error is exponentially convergent to 0, we get the desired index \( k = \mathcal{O}(\log(1/\epsilon)) \) or equivalently there is a \( k \in \mathcal{O}(\|\epsilon\|) \) that yields the approximation \( P_k \) within error \( \epsilon \) of \( \exp(M/m) \).
(3) Finally we keep squaring $\exp(M/m)$ by computing the powers $P_k^l$ for $l = 1, 2, \ldots, \log(m)$ in turn, and eventually get the approximation $P_k^m$ of $\exp(M)$, which costs $\log(m)$ times of matrix multiplication.

Hence, the approximately calculating procedure is in

$$O(K \cdot (k + \log(m)) \cdot N^6) = O(K \cdot (\|\epsilon\| + \log(N)) \cdot N^6).$$

At least a factor $N^4$ in the complexity of the exactly calculating procedure is saved here.

4. Checking Continuous Stochastic Logic

We introduce the continuous stochastic logic (CSL for short) that consists of three layers: i) state formulas (which can be true or false in a specific classical state), ii) path formulas (which can be true or false along a specific path), and iii) model formulas (true or false for a specific model). Then we present an algebraic algorithm for checking the CSL formulas over quantum CTMCs.

**Definition 4.1.** The syntax of the CSL formulas, consisting of state formulas $\Phi$, path formulas $\phi$, and model formulas $\chi$, are defined as follows:

$\Phi := a \mid \neg \Phi \mid \Phi_1 \land \Phi_2$

$\phi := \Phi_0 U I_0 \Phi_1 U I_1 \Phi_2 \cdots U I_{K-1} \Phi_K$

$\chi := P_{\sim c} (\phi)$

where $a \in AP$ is an atomic proposition, $I_k \subseteq \mathbb{R}_{\geq 0}$ ($0 \leq k < K$) are time intervals with rational endpoints, $\sim \in \{=, <, >\}$ is a comparison operator, and $c \in [0, 1] \cap \mathbb{Q}$ is a probability threshold.

In particular, the CSL formula is referred to as the model formula $\chi$. For convenience, we assume that those time intervals $I_k$ are disjoint left-open and right-closed intervals $(a_k, b_k]$, and $b_{K-1}$ is allowed to be $\infty$. Otherwise some detailed techniques could be introduced to deal with as in [ZJNH12, Section 5]. The path formula $\phi$ is called the multiphase until formula to be interpreted below.

Following [ASSB96, BHHK00], we give the formal semantics of CSL.

**Definition 4.2.** The semantics of CSL interpreted over a quantum CTMC $Q = (S, Q, L)$ is given by the satisfaction relation $\models$:

$s \models a$ if $a \in L(s)$;

$s \models \neg \Phi$ if $s \not\models \Phi$;

$s \models \Phi_1 \land \Phi_2$ if $s \models \Phi_1$ and $s \models \Phi_2$;

$\omega \models \Phi_0 U I_0 \Phi_1 U I_1 \Phi_2 \cdots U I_{K-1} \Phi_K$ if there exist $t_0 < t_1 < \cdots < t_{K-1}$ such that for each integer $0 \leq k < K$, we have $t_k \in I_k$ and $\forall t' \in [t_{k-1}, t_k) : \omega(t') \models \Phi_k$ where $t_{-1}$ is defined to be zero, and additionally $\omega(t_{K-1}) \models \Phi_K$;

$\Omega \models P_{\sim c} (\phi)$ if $\Pr(\{\omega : \omega \models \phi\}) \sim c$.

Here, the real numbers $t_1, \ldots, t_{K-1}$ in the interpretation of the multiphase until formula $\phi$ are switch time-stamps, and the time intervals $I_k$ ($0 \leq k < K$) in $\phi$ are absolute timing that are measured from the start of the path, which differs from the LTL interpretation of
the nested until formula with the \textit{relative} timing that are measured from the instants when the prior transitions take place.

The core of the model-checking algorithm lies in measuring all the paths satisfying the multiphase until formula \( \phi \), which can be tackled by the following lemma. Before that, we define the following four notions.

1. Let \( P_\phi := \sum_{s:\Rightarrow \phi} |s\rangle\langle s| \otimes I \) be the projector for some state formula \( \Phi \), and \( P_\phi = P_\phi \otimes P_\phi \).
2. The transition generator function \( Q_\phi \) is given by the Hermitian operator \( H_\phi := H \cdot P_\phi \) and the finite set of linear operators \( L_{\Phi,j} := L_j P_\phi \). Then, the governing matrix \( M_\phi \) adapted for \( Q_\phi \) is

\[
- tH_\phi \otimes I + iI \otimes H_\phi^T + \sum_{j=1}^{m} \left( L_{\Phi,j} \otimes L_{\Phi,j}^* - \frac{1}{2}L_{\Phi,j}^T L_{\Phi,j} \otimes I - \frac{1}{2}I \otimes L_{\Phi,j}^T L_{\Phi,j}^* \right). \tag{4.1}
\]

The transition generator function \( Q_\phi \) and the corresponding governing matrix \( M_\phi \) keep the behaviors from the \( \Phi \)-states and absorb the other states.

3. Recall in probability theory that for an exponentially distributed random variable with rate parameter \( \kappa \), the \textit{cumulative distribution function} \( \text{CDF}(t) = 1 - \exp(\kappa t) \) that determines the probability of the random variable bounded from above by \( t \). So the change in the probability for the random variable falling into a time interval \( (a, b] \) is \( \text{CDF}(b) - \text{CDF}(a) = \exp(\kappa a) - \exp(\kappa b) \). Correspondingly, the matrix exponential \( \exp(Mt) \) is the state transition function that determines the change in the density operator representing ID in a quantum CTMC.

4. Again, in probability theory, the \textit{probability density function} \( \text{PDF}(t) = \kappa \exp(\kappa t) \) that determines the change rate in the probability of the random variable, since \( \text{CDF}(b) - \text{CDF}(a) = \int_a^b \text{PDF}(t) \, dt \). Correspondingly, \( M \cdot \exp(Mt) \) determines the change rate in the density operator.

They are powerful tools to develop the algorithm for checking the CSL formula over quantum CTMCs, together with definite integrals as those for classical CTMCs in [XZJ\textsuperscript{16}].

\textbf{Lemma 4.3.} For a multiphase until formula \( \phi = \Phi_0 U^1 \Phi_1 U^2 \Phi_2 \cdots U^k \Phi_K \), the final partial density operator \( \rho^{(K)} \) measuring all the paths that satisfy \( \phi \) can be calculated inductively by

\[
L^2 V(\rho^{(k)}) = \begin{cases}
P_{\Phi_0} \cdot L^2 V(\rho(0)) & k = 0, \\
P_{\Phi_k} \cdot \left[ \exp(M_{\Phi_{k-1}}(b_k - b_{k-1})) + \int_{a_k}^{b_k} \exp(M_{\Phi_k}(b_k - t_k)) \, dI_t \cdot \right. \\
\left. P_{\Phi_{k-1}} \cdot \exp(M_{\Phi_{k-1}}(t_k - a_k)) \right] \cdot L^2 V(\rho^{(k-1)}) & if \, 0 < k < K, \\
P_{\Phi_k} \cdot \left[ \exp(M_{\Phi_{k-1}}(a_k - b_{k-1})) \cdot \left[ \exp(M_{\Phi_{k-1}}(b_k - a_k)) \cdot P_{\Phi_{k-1}} + P_{\Phi_{k-1}} \right] \right] \cdot \\
\left. \exp(M_{\Phi_{k-1}}(a_k - b_{k-1})) \right] \cdot L^2 V(\rho^{(k-1)}) & if \, k = K,
\end{cases}
\tag{4.2}
\]

where \( a_k = \inf I_k \), \( b_k = \sup I_k \) and \( b_0 \) is defined to be zero for convenience; and thus the satisfaction probability \( \Pr\{ \omega : \omega \models \phi \} \) is \( \text{tr}(\rho^{(K)}) \).

\textbf{Proof.} We prove it by an induction on the phase index \( k \).

Initially, \( \rho^{(0)} \) is the partial density operator \( \sum_{s:\Rightarrow \phi_0} |s\rangle\langle s| \otimes \rho_s \) extracted from \( \rho(0) = \sum_{s \in \Sigma} |s\rangle\langle s| \otimes \rho_s \) by the projector \( P_{\Phi_0} \) (see Notion 1), which measures the paths that satisfy \( \phi \) at time 0.
Let \( \rho^{(k-1)} (k < K) \) be the partial density operator measuring the paths that satisfy \( \phi \) up to time \( b_{k-1} \). We proceed to construct the partial density operator \( \rho^{(k)} \) measuring the paths that satisfy \( \phi \) up to time \( b_k \) as follows. Based on the semantics of the \( k \)th phase of \( \phi \), all the paths that satisfy \( \phi \) can be classified into two disjoint path sets:

- one contains the paths leaving \( \Phi_{k-1} \)-states for \( \Phi_k \)-ones during \( I_k \), i.e., for some switch time-stamp \( t_k \in I_k = (a_k, b_k) \),

\[
\{ \omega: [\forall t' \in (b_{k-1}, t_k): \omega(t') = \Phi_{k-1}] \land [\omega(t_k) = -\Phi_{k-1}] \land [\forall t'' \in [t_k, b_k]: \omega(t'') = \Phi_k] \},
\]

- the other contains the paths that do not have to leave \( \Phi_{k-1} \)-states during \( I_k \), i.e., \( \{ \omega: [\forall t' \in (b_{k-1}, b_k): \omega(t') = \Phi_{k-1}] \land [\omega(b_k) = \Phi_k] \} \).

Here, “leaving \( \Phi_{k-1} \)-states” means that the path \( \omega \) satisfies \( \phi \) but at some \( t \in I_k \), \( \omega(t) \) dissatisfies \( \Phi_{k-1} \) and it must enter into \( \Phi_k \)-states then. Correspondingly, the former path set is measured by the partial density operator

\[
V2L \left( P_{\Phi_k} \cdot \int_{a_k}^{b_k} \exp(M_{\Phi_k}(b_k - t_k)) \cdot P_{-\Phi_{k-1}} \cdot M_{\Phi_{k-1}} \cdot \exp(M_{\Phi_{k-1}}(t_k - a_k)) \, dt_k \right)
\]

where

- \( M_{\Phi_{k-1}} \) and \( M_{\Phi_k} \) are the governing matrices respectively adapted to \( Q_{\Phi_{k-1}} \) and \( Q_{\Phi_k} \) (see Notion 2),

- \( \exp(M_{\Phi_{k-1}}(a_k - b_{k-1})) \) and \( \exp(M_{\Phi_k}(b_k - t_k)) \) are the state transition functions (see Notion 3), and

- \( M_{\Phi_{k-1}} \cdot \exp(M_{\Phi_{k-1}}(t_k - a_k)) \) gives the rate of state transition (see Notion 4).

The latter path set is measured by the partial density operator \( V2L(P_{\Phi_k} \cdot \exp(M_{\Phi_{k-1}}(b_k - b_{k-1})) \cdot L2V(\rho^{(k-1)})) \). Since the two path sets are disjoint, \( \rho^{(k)} \) is the sum of the above two partial density operators.

Let \( \rho^{(K-1)} \) be the partial density operator measuring the paths that satisfy \( \phi \) up to time \( b_{K-1} \). We proceed to construct the partial density operator \( \rho^{(K)} \) measuring the paths that satisfy \( \phi \) up to time \( b_K \) as follows. Based on the semantics of the \( K \)th phase of \( \phi \), all the paths that satisfy \( \phi \) are classified into two disjoint sets:

- one is not immediately reaching \( \Phi_K \)-states during \( I_K \), i.e., for some switch time-stamp \( t_K \in I_K = (a_K, b_K) \),

\[
\{ \omega: [\forall t' \in [b_{K-1}, t_K): \omega(t') = \Phi_{K-1}] \land [\forall t'' \in [a_K, t_K): \omega(t'') = -\Phi_K] \land [\omega(t_K) = \Phi_K] \}
\]

- the other is immediately reaching \( \Phi_K \)-states at \( a_K \), i.e., \( \{ \omega: [\forall t' \in [b_{K-1}, a_K): \omega(t') = \Phi_{K-1}] \land [\omega(a_K) = \Phi_K] \} \).

Here, “not immediately reaching \( \Phi_K \)-states” means that the satisfying path \( \omega \) dissatisfies \( \Phi_K \) at \( a_K \), and it enters in \( \Phi_K \)-states for some \( t > a_K \). Correspondingly, the two disjoint path sets are measured by the partial density operators:

\[
V2L(P_{\Phi_k} \cdot \exp(M_{\Phi_{k-1}}(b_k - a_k)) \cdot P_{-\Phi_k} \cdot \exp(M_{\Phi_{k-1}}(a_k - b_{k-1})) \cdot L2V(\rho^{(k-1)}))
\]

\[
V2L(P_{\Phi_k} \cdot \exp(M_{\Phi_{k-1}}(a_k - b_{k-1})) \cdot L2V(\rho^{(k-1)})),
\]

whose sum is exactly \( \rho^{(K)} \). Hence \( \rho^{(K)} \) is the final partial density operator measuring the paths that satisfy the whole path formula \( \phi \).
When tackling $b_K = \infty$, we do not suffer from the trouble that the bottom strongly connected component (BSCC) subspaces will make the orbit of density operators periodical, since the probability $\text{tr}(\rho^K)$ of satisfying $\phi$ is monotonically increasing along $b_K$. So it can be achieved by taking the limit.

**Example 4.4.** The percolation performance is an essential property of networks that describes transitions between nodes and their neighborhood. Reconsidering the first generation of AN in Example 3.3, the return probability of the center node reflects the percolation performance. We aim to compute the probability of the following return event.

*The qutrit starts at the center node, then transits to non-center nodes in one unit of time and sojourns there up to (absolute) time at least 1, and finally returns to the center node within time 2.*

This could be formally specified by the CSL formula $\phi_1 \equiv \Phi_0 U_{I_1}^1 \Phi_1 U_{I_2} \Phi_2$, where $\Phi_0 \equiv \Phi_2 \equiv \text{center}$, $\Phi_1 \equiv \neg \text{center}$, and time intervals $I_1 = (0, 1]$ and $I_2 = (1, 2]$. Firstly, we take $\rho(0) = |3\rangle\langle 3| \otimes \frac{1}{3}I$ and define

\[
\begin{align*}
P_{\Phi_0} &= P_{\Phi_2} = P_{\Phi_0} \otimes P_{\Phi_0} = (|3\rangle\langle 3| \otimes I) \otimes (|3\rangle\langle 3| \otimes I), \\
P_{\Phi_1} &= P_{\neg \Phi_0} = P_{\Phi_1 \land \neg \Phi_2} = P_{\Phi_1} \otimes P_{\Phi_1} \\
&= (|0\rangle\langle 0| + |1\rangle\langle 1| + |2\rangle\langle 2|) \otimes I \otimes [(|0\rangle\langle 0| + |1\rangle\langle 1| + |2\rangle\langle 2|) \otimes I], \\
M_{\Phi_i} &= \sum_{j=1}^{12} [(L_j P_{\Phi_i}) \otimes (L_j P_{\Phi_i})^\dagger (L_j P_{\Phi_i}) (L_j P_{\Phi_i})^\dagger (L_j P_{\Phi_i})] - \frac{1}{2} (L_j P_{\Phi_i}) (L_j P_{\Phi_i})^\dagger (L_j P_{\Phi_i})^\dagger (L_j P_{\Phi_i})^\dagger I - \frac{1}{2} I \otimes (L_j P_{\Phi_i})^\dagger (L_j P_{\Phi_i})^\dagger (\Phi_i^\dagger) ,
\end{align*}
\]

for $i = 0$ or 1. Then, we calculate $\rho^{(2)}$ in an inductive fashion:

\[
\begin{align*}
L_2 V(\rho^{(0)}) &= P_{\Phi_0} \cdot L_2 V(\rho(0)), \\
L_2 V(\rho^{(1)}) &= P_{\Phi_1} \cdot [\exp(M_{\Phi_0}(1 - 0)) + \int_0^1 \exp(M_{\Phi_1}(1 - t_1)) \cdot P_{\neg \Phi_0} \cdot M_{\Phi_0} \cdot \\
&\quad \cdot \exp(M_{\Phi_0}(t_1 - 0)) \cdot d t_1 \cdot P_{\Phi_0} \cdot \exp(M_{\Phi_0}(0 - 0))] \cdot L_2 V(\rho^{(0)}), \\
L_2 V(\rho^{(2)}) &= [P_{\Phi_2} \cdot \exp(M_{\Phi_1 \land \neg \Phi_2}(2 - 1)) + P_{\Phi_2}] \cdot P_{\Phi_1} \cdot \exp(M_{\Phi_1}(1 - 1)) \cdot L_2 V(\rho^{(1)}).
\end{align*}
\]

The result is $\rho^{(2)} = |3\rangle\langle 3| \otimes \rho_3$ with computable partial density operator $\rho_3$ on $\mathcal{H}$. We replace the definite integral with the Riemann sum under a predefined step length, saying $\frac{1}{100}$,

\[
\begin{align*}
\frac{1}{100} \sum_{i=1}^{100} \exp(M_{\Phi_1 \frac{100 - i}{100}}) \cdot P_{\neg \Phi_0} \cdot M_{\Phi_0} \cdot \exp(M_{\Phi_0 \frac{i}{100}}),
\end{align*}
\]

and get the numerical approximation

\[
\begin{align*}
\rho_3 &\approx 0.105266[|0\rangle\langle 0| + |1\rangle\langle 1| + |2\rangle\langle 2|] + (-0.052633 + 0.091163i)[|0\rangle\langle 1| + |1\rangle\langle 2| + |2\rangle\langle 0|] + \\
&\quad (+0.052633 - 0.091163i)[|0\rangle\langle 2| + |2\rangle\langle 0| + |1\rangle\langle 1|].
\end{align*}
\]

Thus we obtain the return probability $\text{Pr}(\phi) = \text{tr}(\rho^{(2)}) = \text{tr}(\rho_3) \approx 0.315798$. □
Theorem 4.5. The CSL formula is decidable over quantum CTMCs.

Proof. Using Jordan decomposition, matrix exponentiation and integration-by-parts, we first claim that the satisfaction probability can be expressed as a number in the explicit form

\[ p = \alpha_1 e^{\lambda_1} + \alpha_2 e^{\lambda_2} + \cdots + \alpha_m e^{\lambda_m}, \]

where \( \alpha_1, \ldots, \alpha_m \) are algebraic numbers and \( \lambda_1, \ldots, \lambda_m \) are distinct algebraic numbers. We observe the facts:

1. The governing matrix \( M_\Phi \) appearing in Eq. (4.2) (see its definition in Eq. (4.1)) takes algebraic numbers as entries, since the entries of \( H_s \) and \( L_{s_1, s_2} \) are algebraic.
2. The characteristic polynomial of \( M_\Phi \) is an \( \mathbb{A} \)-polynomial. The eigenvalues \( \lambda_1, \ldots, \lambda_m \) of \( M_\Phi \) are algebraic, as they are roots of that \( \mathbb{A} \)-polynomial by Lemma 2.4. Those eigenvalues will make up all exponents in Eq. (4.3) afterwards.
3. By Jordan decomposition, we have \( M_\Phi = T \cdot J \cdot T^{-1} \), where the Jordan canonical form \( J \) has entries 0, 1, and those eigenvalues \( \lambda_i \), and the transformation matrix \( T \) takes linear expressions with \( \mathbb{A} \)-coefficients over entries of \( J \) as its entries, which are algebraic too.
4. Since \( \exp(M_\Phi \cdot a) = T \cdot \exp(J \cdot a) \cdot T^{-1} \), we have that the entries of \( \exp(J \cdot a) \) are with the form \( (\lambda_i a)^k e^{\lambda_i a} / k! \) for some integer \( k \). Thus the matrix exponential \( \exp(M_\Phi \cdot a) \) takes linear expressions with \( \mathbb{A} \)-coefficients over \( (\lambda_i a)^k e^{\lambda_i a} / k! \) as its entries.
5. When \( a \) is an algebraic constant that is taken from the endpoints of \( \mathcal{I}_k \), the entries of \( \exp(M_\Phi \cdot a) \) are in the form (4.3). Whereas, \( \exp(M_\Phi \cdot t) \) takes linear expressions with \( \mathbb{A} \)-coefficients over \( (\lambda_i t)^k e^{\lambda_i t} / k! \) as its entries.
6. The same structure holds for entries of the indefinite integral

\[ \int \exp(M_\Phi(b_k - t_k)) \cdot P_{-\Phi_{k-1}} \cdot M_{\Phi_{k-1}} \cdot \exp(M_{\Phi_{k-1}}(t_k - a_k)) \, d t_k, \]

which follows integration-by-parts that for any polynomial \( q(t) \), there is a polynomial \( r(t) \) with \( \deg(r) = \deg(q) \), such that \( \int q(t) e^{\lambda_t} \, d t = r(t) e^{\lambda_t} \). Finally, we can see that the
entries of the definite integral
\[ \int_{a_k}^{b_k} \exp(M_{\phi_k}(b_k - t_k)) \cdot P_{\phi_{k-1}} \cdot M_{\phi_{k-1}} \cdot \exp(M_{\phi_{k-1}}(t_k - a_k)) \, dt_k \]
are in the form (4.3).

By Theorem 2.5, we have that \( p = c \) if and only if \( m = 1, \lambda_1 = 0 \) and \( \alpha_1 = c \). If not, we further compute the value \( p \) up to any precision by sufficiently approaching the Euler constant \( e \), and thereby compare \( p \) with \( c \), which decides the truth of \( \Omega \models P_{\sim c}(\phi) \).

**Complexity.** The decision algorithm is in time polynomial in the encoding size of the input quantum CTMC and linear in the size of the input CSL formula, besides the query/oracle — how sufficiently the Euler constant \( e \) should be approached. Whereas, the satisfaction probability can be computed in polynomial time using the numerical methods — the scaling and squaring method embedded with Padé approximations and the Riemann sum.

5. Concluding Remarks

This paper introduced a novel model of quantum CTMC consisting of a classical subsystem and a quantum subsystem. The essential difference of these two systems lies in that a quantum system allows superpositions while a classical system not. The classical subsystem in the current model forbids superpositions, making it more precise than the model of quantum CTMC proposed in [XMGY21], which does not take this point into consideration. Then we checked the famous branching logic — CSL — against the quantum CTMC. The decidability is established by an algebraic approach to tackling multiphase until formulas, which lie at the core of CSL. To be more efficient, numerical methods could be incorporated to yield a polynomial-time procedure. Furthermore, we provided the Apollonian network as a running example to demonstrate the method mentioned above.

For future work, an interesting direction is model-checking the quantum continuous-time Markov decision processes (CTMDP) [YY18], in which probabilistic and nondeterministic behaviors coexist. To resolve nondeterminism, following the verification work [Mil68, MSS20] in classical CTMDPs, an optimal scheduler is expected to maximize the probability of a given property over almost all time-stamps at each classical state. Here, it follows that local optimization yields global optimization. In quantum systems, however, there are additionally quantum states that are described by density operators. The known way to compare density operators \( \rho \) are based on the Löwner partial order \( \subseteq \), i.e., \( \rho_1 \subseteq \rho_2 \) if \( \rho_2 - \rho_1 \) is positive. Thus local optimization does not yield global optimization generally, which will bring nontrivial technical hardness to be resolved.

The presented method has been implemented in the Wolfram language on Mathematica 12.1 with Intel Core i7-10700 CPU at 2.90GHz. We deliver it as user-friendly functions in the file Functions.nb available at https://github.com/meijingyi/CheckQCTMC. The main functions are listed below.

- **ExpSS** computes the matrix exponential, as a subroutine from MATLAB, using the scaling and squaring method [AMH09].
- **GovernMat** computes the governing matrix $M_\Phi$ which keeps the behavior of $\Phi$-states and absorbs others.
- **Cyl** gets the final partial density operator in \ref{eq:3.2} while computing the probability measure along a given cylinder set.
- **Multiphase** gets the final partial density operator in \ref{eq:4.2} while computing the probability measure of a multiphase until formula.

For the function **ExpSS**, there is a useful tool MATLink available to transfer data between Mathematica and MATLAB, thus we can use the embedded function `expm` in MATLAB. After specifying a quantum CTMC model $Q$ attached with the Hilbert space and a multiphase until formula $\phi$, one can perform the model-checking by calling the above functions respectively. The running examples are validated in the file Appollonian Network.nb. Notably, using the scaling and squaring method for matrix exponentiation, the time and the space consumption of computing the probabilities of the cylinder set in Example 3.5 and the multiphase until formula in Example 4.4 are summarized in Table 1.
Table 1. Performance using the scaling and squaring method

| method | Cyl | Multiphase | Overall |
|-------|-----|------------|---------|
|       | time | memory     | time    | memory    |
| ExpSS | 0.44s| 4.60MB     | 4.80s   | 36.54MB   | 5.375s  | 176.531MB |
